The Helmholtz resonator is a good example of a resonating air cavity. It is basically a hollow sphere with a circular opening (with a diameter of the order of one-tenth that of the sphere) and usually equipped with a very short neck. An acoustic source brought near the resonator can set the air in the opening in vibration. The action then is effectively that of a simple vibrating system of mass equal to that of the moving plug of air in the orifice, of stiffness provided by the elasticity of the air cushion inside the sphere, and of resistance largely due to the radiation of sound energy from the opening. Analysis indicates that the appropriate elements are respectively

$$\begin{aligned} m &= \rho_0 S^2/C \\ f &= \rho_0 c^2 S^2/V \\ R &= \rho_0 \omega^2 S^2/2\pi c \end{aligned} \quad (107)$$

where ρ_0 is the density of the air, V the volume of the resonator sphere, S the cross-sectional area of the opening, C the acoustic conductivity of the opening, and c the acoustic velocity in air. The resonance angular frequency of the resonator is approximately

$$\omega_{res} = c\sqrt{C/V} \quad (108)$$

The amplification A of the resonator is defined to be the ratio of the square of the excess pressure amplitude in the opening to that present at the same point in the absence of the resonator. At resonance this has the form

$$A = 4\pi^2 V/C^3 \quad (109)$$

Resonators serve as useful acoustic amplifiers (for single frequencies) for numerous types of sound sources and receivers.

5. Membranes.—A vibrating circular membrane is a more practical source of sound of high intensity than a vibrating string since it is two-dimensional. The equation of motion of a perfectly flexible membrane stretched with surface tension S (force per unit length across the membrane) and surface density ρ_s (mass per unit area) is of the form

$$\frac{S}{\rho_s}\left(\frac{\partial^2 \xi}{\partial x^2} + \frac{\partial^2 \xi}{\partial y^2}\right) = \ddot{\xi} \quad (110)$$

if the equilibrium position of the membrane is in the xy plane and ξ denotes a displacement perpendicular to this plane. If the membrane is circular it is simpler to replace x and y by the polar coordinates r and θ and write equation (110) in the form

$$\frac{\partial^2 \xi}{\partial r^2} + \frac{\partial \xi}{r \partial r} + \frac{\partial^2 \xi}{r^2 \partial \theta^2} = \frac{1}{c^2}\ddot{\xi} \quad (111)$$

with the velocity

$$c = \sqrt{S/\rho_s} \quad (112)$$

The solutions of equation (111) are complicated and will not be given here. It is of interest, however, to note the normal modes of oscillation of a membrane of radius a rigidly clamped around its periphery, since many membrane sound sources are used in this way. The three lowest harmonics have frequencies

$$\nu_1 = \frac{0.77c}{2a},\ \nu_2 = \frac{1.22c}{2a},\ \nu_3 = \frac{1.76c}{2a} \quad (113)$$

where the fundamental is ν_1. The higher modes do not form a harmonic series in the sense of the characteristic frequencies of the vibrating string or tube. The standing waves that correspond to the normal modes of the clamped vibrating membrane have nodal lines similar to the nodal points in the string or tube. These are both circles and radii that can be experimentally demonstrated by covering the vibrating membrane with lycopodium powder which tends to collect along the nodal lines.

For practical purposes it is often sufficiently accurate to consider a circular membrane clamped at the periphery and vibrating in its fundamental mode as equivalent to a vibrating piston in which all points have the same displacement and velocity at the same instant. This piston may be thought of as having effective mass m and effective stiffness f, so that its resonance frequency is given by equation (101). Using the approximation that in the fundamental mode the shape of the displaced membrane is approximately paraboloidal, the effective mass is one-third of the actual mass and the effective stiffness is 2π times the surface tension S. The fundamental frequency given by equation (101) in this case is only about 1% higher than 0.77 $c/2a$ as shown in equations (113).

6. Longitudinal Vibrations of Rods.—For a straight rod of uniform cross section, the length of which is very large compared with its diameter, the differential equation of motion for a small extensional disturbance ξ (*i.e.*, directed along the rod) is

$$\ddot{\xi} = Y/\rho_0 \cdot \partial^2\xi/\partial x^2 \quad (114)$$

in which Y is Young's modulus and ρ_0 is the actual volume density. The disturbance thus travels along the rod as a longitudinal wave with velocity

$$c = \sqrt{Y/\rho_0} \quad (115)$$

For most hard solids this velocity is of the order of 3,000 m. per sec., though it ranges from about 1,000 to 6,000 m. per sec., depending on density and elasticity.

The specific acoustic resistance for a longitudinal wave in a solid rod is $\rho_0 c$, as in the case of compressional waves in a fluid.

A finite vibrating rod serving as a source of sound must satisfy certain boundary conditions. These will lead to the production of

standing waves as in the case of air vibrations in a tube. Thus if the rod vibrates so that both ends are rigidly clamped, it requires that $\xi = 0$ at $x = 0, l$ (if l is the length of the rod). This leads to the normal modes or characteristic frequencies

$$\nu_n = nc/2l \tag{116}$$

the fundamental corresponding to $n = 1$.

On the other hand if one end of the rod only is clamped and the other end is left free, the corresponding frequencies are

$$\nu_n' = (n + \tfrac{1}{2})\, c/2l \tag{117}$$

A common case is that in which the rod is clamped at the middle. The fundamental frequency is still given by $c/2l$, since this provides for a displacement node at the centre. However, in this case the even harmonics are absent since they do not have nodes at the centre, and rigid clamping at the centre must always correspond to a node there.

The modes of oscillation of a longitudinally vibrating rod are usually studied by sprinkling the rod with lycopodium powder which gathers at the nodes, thus permitting the measurement of wavelength and (through knowledge of the driving frequency) the longitudinal wave velocity. If the transverse dimensions of the rod are not negligible compared with the length, wave transmission along the rod is much more complicated and equation (115) no longer holds. When an elastic rod is stretched there also must be a change in cross-sectional area. This leads to radial vibrations and the coupling between these and the longitudinal variety may be expected to lead to complicating effects, especially when the wavelength of the longitudinal wave is of the order of magnitude of the transverse diameter. For very low frequencies with corresponding long wavelengths the coupling between the two types of mode is weak and the velocity of equation (115) is observed. But as the frequency increases, say to 200 kc. for a rod in which the diameter is 1 cm., the effective longitudinal velocity drops noticeably from the value given by equation (115). This is a type of dispersion; *i.e.*, change of velocity with frequency. It may be called configurational, since it is associated with the finite transverse dimensions of the rod rather than with internal molecular effects. As the frequency is further increased, say to 500 kc. in the case of the rod just mentioned, the velocity falls asymptotically to the value for shear or torsional waves in the rod: $c = \sqrt{\mu/\rho_0}$, where μ is the rigidity or shear modulus. Further increase of frequency produces little change. A complete explanation of these effects demands a complicated analysis of elastic wave propagation under the appropriate boundary conditions.

Just as in elastic wave propagation in a fluid, so also in a solid there are dissipative effects that lead to absorption of the wave energy with a loss of intensity. In analogy with the discussion for equation (61), the displacement from equilibrium in a harmonic longitudinal disturbance propagated along the rod may be written

$$\xi = \xi_0 e^{-\alpha x} \cos(\omega t - kx) \tag{118}$$

where ω ($= 2\pi\nu$) is the angular frequency of the wave and α is the absorption coefficient. For most solid rods at frequencies above a few cycles per second, α is not proportional to the square of the frequency as in the case of liquids and gases but more nearly approximates a linear dependence. For polycrystalline media (with metallic grains) this is corrected by an additional term depending on the fourth power of the frequency. Thus for polycrystalline aluminum, Mason and H. J. McSkimin found

$$\alpha = a_1\nu + a_2\nu^4 \tag{119}$$

with $a_1 = 0.845 \times 10^{-9}$ sec/cm, $a_2 = 3.74 \times 10^{-30}$ sec^4/cm. The linear dependence on the frequency is thought to have its origin in internal friction or solid viscosity (which evidently operates in a different way from the viscosity of fluids), whereas the fourth-power dependence is associated with a scattering of the elastic wave by the metallic grains of which the polycrystalline material is composed. This scattering is analogous to that which in the case of light is considered to account for the blue colour of the sky. Equation (119) was found to work well in the frequency range from 2 to 15 Mc. per sec.

Equation (118) expresses absorption of a longitudinal harmonic wave in a solid in terms of the amplitude decay with distance of travel. The absorption may also be expressed in terms of decay in time. This is a more appropriate way to express it in a finite rod, set freely vibrating by some energy source and then set free from the energy source and allowed to die down. In this case the expression for the displacement at any place x at time t in a progressive harmonic wave in the positive x direction is

$$\xi = \xi_0 e^{-\beta t} \cos(\omega t - kx) \tag{120}$$

in which β is a kind of temporal absorption coefficient. At any particular point on the rod (definite value of x) the displacement behaves like a damped harmonic oscillator. The logarithmic decrement is

$$\delta = \beta P = \pi/Q \tag{121}$$

where P ($= 1/\nu$) is the period of the wave; the quality factor Q was introduced in equation (92). Still another way of referring to the attenuation is to use the average fractional loss of energy W in the radiation per unit volume for one cycle of the harmonic disturbance. Since the energy per unit volume is proportional to the square of the amplitude,

$$W = 2\beta P = 2\delta \tag{122}$$

It can be shown that independent of the precise attenuating mechanism the fractional energy loss can be expressed in the form

$$W = 2\alpha\lambda \tag{123}$$

where λ is the wavelength. This makes it possible to express the decrement and Q value in terms of the absorption coefficient α.

Attenuation also arises from the friction drag of the surrounding fluid medium on the vibrating surface of the rod. This is generally smaller than that from internal friction. The rod also radiates sound energy to the surrounding medium; this accounts for loss of energy in the vibrations. This effect is also very small except at very high frequency. In other words, at low frequencies a vibrating rod is not a very efficient acoustic source unless it is coupled to a membrane or diaphragm with a larger radiating surface.

Transmission in solid rods, mainly at ultrasonic frequencies, has been studied to learn more about the physical properties of the solid material; *e.g.*, its elastic constants. Thus equation (115) permits the evaluation of Young's modulus Y from a knowledge of the density ρ and the velocity c of longitudinal waves in the rod, provided the frequency used is such that the wavelength is considerably larger than the width or diameter of the rod (if circular). High-frequency waves are particularly suitable for this purpose, since the wavelength can be long enough to satisfy the requirement just stated and still short enough to permit its measurement by a powder pattern on the rod produced by standing waves.

For optically transparent solids the determination of elastic constants is easiest by an optical technique based on the Debye-Sears effect. If a transparent solid cube is filled with an ultrasonic standing wave pattern produced by a piezoelectric quartz oscillator (*see* section III.11) cemented to one of its faces, and a beam of light is then passed through it, an optical diffraction pattern is formed. If the solid is isotropic the pattern consists of rings that elasticity theory readily associates with the bulk and shear elastic moduli as well as Poisson's ratio σ (*see* section III. 8). For transparent crystalline solids the same method is applicable, though the patterns are more complicated.

For the study of transmission through solid rods and other extended solids, pulse techniques are often more practical than standing wave patterns, especially if the solids are optically opaque. With appropriate electronic equipment it is possible to produce ultrasonic pulses of only a few milliseconds duration and measure with great accuracy their transit time through a solid specimen; in this way velocity can be readily determined. Recall that it is the group velocity that is found in this way. The method is very simple in principle but demands many precautions against errors if high precision is sought.

Acoustic attenuation in a solid can also be measured by the

pulse method by noting the relative amplitudes of the initial pulse and that returning to the source after a double transit of the specimen under study. When rubberlike materials are investigated by this method, considerable velocity dispersion is found. Thus for natural rubber at 0° C the velocity ranges from about 1,800 m. per sec. at 0.1 Mc. to about 2,700 m. per sec. at 10 Mc. The dispersion decreases as the temperature is raised. Attenuation measurements in such materials indicate relaxation mechanisms similar to those for liquids and gases.

Solids at very low temperatures (*i.e.*, below 20° K) became available through the use of liquid helium. Particular attention has been paid to those solids that become superconducting at low temperatures, such as lead, tin, and indium. These metals appear to lose all electrical resistance at temperatures near 4° K. Thus tin becomes superconducting below 3.73° K, its so-called transition temperature. If ultrasonic radiation (*e.g.*, at 10 Mc.) is passed through a rod of such a superconducting metal, attenuation above the transition temperature increases as temperature decreases until the transition temperature is reached, when a sharp discontinuity in slope appears, and as the temperature is lowered attenuation decreases rapidly. On the other hand, if a magnetic field is imposed on the specimen, superconductivity is destroyed and attenuation continues to increase as the temperature falls below the normal transition point. It thus appears that the acoustic attenuation arises from a mechanism closely related to that responsible for the superconductivity. It should be remembered that a metal crystal consists of a more or less stable lattice of positive ions and a collection of readily mobile, more or less free conduction electrons that are responsible for electrical conductivity. The lattice ions are never wholly motionless, but vibrate about their mean positions; above the transition temperature they can exchange energy with the conduction electrons. When a high-frequency sound wave passes through the metal energy exchange is increased, and this leads to attenuation. Evidently this cannot happen in the superconducting state. It was believed in the 1960s that in this state it is more difficult to transfer energy from lattice to electrons and the attenuation mechanism ceases to work.

At temperatures well above the superconducting transition and for nonsuperconductors other relaxation mechanisms lead to acoustic attenuation in solids. These are related to imperfections in the lattice of which dislocations (*i.e.*, displacements of one layer of metal ions relative to the adjoining one) are examples (*see* CRYSTALS, DISLOCATION OF).

7. Flexural and Torsional Vibrations of Rods.—Of possibly more practical importance than longitudinal vibrations are the bending variety in which the propagated disturbance is a flexure at right angles to the length of the rod.

The disturbance in this case is no longer propagated in accordance with the simple wave equation (6). Nevertheless, it can be shown that the flexure can move along the rod as a simple harmonic wave provided the velocity is a function of frequency; *i.e.*, the bending rod acts as a dispersive medium. The phase velocity is found to have the form (H. Lamb)

$$c = \frac{kK}{\sqrt{1+k^2K^2}}\cdot\sqrt{\frac{Y}{\rho_0}} \tag{124}$$

where Y is Young's (or the stretch) modulus of the rod and K is the radius of gyration of the cross-sectional area about an axis through its centre of symmetry normal to the plane of flexure. As usual k is the wave parameter. Wave energy is transmitted by flexure along the rod with the group velocity

$$U = 2c - \frac{k^3K^3\sqrt{Y/\rho_0}}{(1+k^2K^2)^{3/2}} \tag{125}$$

For very low frequencies for which $k^2K^2 < < 1$ the wave velocity c is a small fraction of $\sqrt{Y/\rho_0}$ the velocity of longitudinal stress waves in the rod; the group velocity U is very nearly twice c. For very high frequencies for which $k^2K^2 > > 1$ wave velocity approaches $\sqrt{Y/\rho_0}$ and U approximates the same value. This neglects radial effects; *i.e.*, the change of cross section accompanying bending as well as extension. When these are taken into account, it is found that as the frequency is increased c rises steadily from zero to an asymptotic value equal again to the velocity of torsional waves in the rod $(\sqrt{\mu/\rho_0})$. This was experimentally verified by S. K. Shear and A. B. Focke (among others).

The greatest interest in the flexural vibrations of rods rests on their use as vibrators for sound sources; *i.e.*, as a finite rod clamped in some specified way. Application of the appropriate boundary conditions yields the fundamental frequencies and overtones. A few samples are indicated here (P. M. Morse):

1. Rod clamped at one end and free at the other
   Fundamental frequency $\nu_f = 0.5596\ K/l^2\cdot\sqrt{Y/\rho_0}$
   First overtone frequency $= 6.267\ \nu_f$
   Second overtone frequency $= 17.55\ \nu_f$
2. Rod clamped at both ends
   Fundamental frequency $\nu_f = 3.56\ K/l^2\cdot\sqrt{Y/\rho_0}$
   First overtone frequency $= 2.76\ \nu_f$
   Second overtone frequency $= 5.40\ \nu_f$

It is clear that the overtones are not harmonics.

A torsional wave results when a twist in a solid circular rod or tube at right angles to the length is propagated lengthwise. If the twist at distance x from a chosen origin is denoted θ (*i.e.*, the angle through which a circular section is turned from its equilibrium position), the wave equation for the torsional wave becomes

$$\ddot{\theta} = \mu/\rho_0\cdot\partial^2\theta/\partial x^2 \tag{126}$$

where μ is again the shear modulus. The velocity of torsional waves is therefore

$$c = \sqrt{\mu/\rho_0} \tag{127}$$

which is less than that for longitudinal waves, though greater in general than for flexural waves. The damping effect of the friction drag of the surrounding medium on flexural and torsional vibrations is much greater than on longitudinal vibrations. As a matter of fact the decay in torsional oscillations of a cylinder in a gas is commonly used to measure the viscosity of the gas.

Wholly aside from the dissipative attenuation produced in elastic waves in solid rods, it is possible to produce wave transmission that is selective with respect to frequency (*i.e.*, filtration) by placing appropriate equally spaced and iterated loads along the rod. Such structures are usually band-pass solid acoustic filters with the lowest frequency band a pass band.

8. Plates and Diaphragms.—A membrane is assumed to have perfect flexibility, but a solid sheet or plate with its greater elastic constants as a rule provides much greater stiffness. Consequently, the velocity of propagation of elastic disturbances in a plate is usually greater than in a membrane. The theory of the vibrations of a plate is very difficult. However, the fundamental normal mode frequency of a circular plate of radius a clamped around the periphery is

$$\nu_f = 1.62\ c^3/a^3 \tag{128}$$

where

$$c = [Yl^2/12\rho_0(1-\sigma^2)]^{1/4} \tag{129}$$

and l is the thickness of the plate, ρ_0 the density of the material of which it is made, and σ is Poisson's ratio (the ratio of the lateral contraction to lengthwise elongation of a bar of the material composing the plate, with a value ranging from 0.2 to 0.4 for most solids). For example, for an iron plate for which $a = 2.2$ cm. and $l = 0.02$ cm., $\nu_f \approx 10^3$ cycles per second. The higher characteristic frequencies are not harmonic and the first few are given (P. M. Morse) as

$$\nu_{11} = 2.09\ \nu_f,\ \nu_{21} = 3.43\ \nu_f,\ \nu_{02} = 3.91\ \nu_f,\ \nu_{31} = 5.98\ \nu_f$$

Comparison with the corresponding case of the flexible membrane shows that the overtones for the plate are more widely spread out than for the membrane.

The vibration theory of plates is so difficult that it is customary to replace the circular diaphragm by an equivalent piston vibrator, all parts of which move in phase. This technique (mentioned in connection with membranes) is strictly justified only when the diaphragm vibrates below its fundamental frequency, so there are no nodal lines or circles.

Interest in the vibrations of solid structures of more or less complicated shape has been stimulated largely through developments in aeronautics and in space vehicles. When exposed to intense aerodynamic acoustic fields, solid surfaces can vibrate with enough intensity to produce serious structural fatigue (*see* FATIGUE OF METALS). The need for reducing vibration has led to the development of ingenious vibration dampers (*e.g.*, layered plates with inserted damping material as in a sandwich).

9. Radiation Efficiency.—If a vibrating system is to serve as an acoustic source it must radiate sound energy. The radiation efficiency of such a source will depend on the properties of the medium as well as those of the source itself. Consider the ideal case of a spherical shell vibrating radially. If the outside radius of the shell is a (with surface area $S = 4\pi a^2$) and it vibrates harmonically with angular frequency ω, the radiation exerts a reaction force that tends to increase the effective mass of the sphere and to increase its effective damping coefficient. As an oscillator in a vacuum the sphere will be characterized by a mechanical mass m, a damping factor R, and a stiffness f. Since it is radiating into a medium of density ρ_0, its mass is effectively increased by

$$m_r = Z_2 S/\omega \qquad (130)$$

and its damping coefficient is effectively increased by

$$R_r = Z_1 S \qquad (131)$$

In these expressions

$$Z_1 = \frac{\omega\rho_0 k a^2}{1 + k^2a^2} \qquad (132)$$

and is called the specific radiation resistance at the surface of the sphere. Also

$$Z_2 = \frac{\omega\rho_0 a}{1 + k^2a^2} \qquad (133)$$

and is called the specific radiation reactance at the surface of the sphere. They are the components of the specific acoustic radiation impedance. The quantity m_r in equation (130) is usually referred to as the radiation inertia, while R_r is called the radiation resistance.

For low frequencies or long wavelengths ($ka << 1$) the radiation inertia becomes the mass of a volume of the medium three times the volume of the vibrating sphere and can be appreciable (affecting, for example, the resonance frequency of the vibration), while the radiation resistance is relatively small. For high frequencies or short wavelengths ($ka >> 1$) the radiation inertia becomes negligibly small and the radiation resistance approaches $4\pi a^2\rho_0 c$. The specific radiation resistance becomes $\rho_0 c$ or the value for a plane wave. The result is that for given velocity amplitude the pulsating sphere is a more powerful acoustic radiator at high frequencies than at low, for dissipation of energy in the form of radiation increases with frequency, as the behaviour of the radiation resistance shows. This is one reason for the interest in ultrasonics.

The pulsating sphere usually is not a practical sound source. However, similar considerations apply to the membrane or diaphragm source in loud-speakers. The result is that for sound sources of all kinds radiation efficiency tends to be greater at high frequencies than at low. At all frequencies the average rate of radiation depends directly on the density of the surrounding medium. This makes it increasingly difficult to get radiation from any source into a medium of much smaller density. This accounts for the famous bell-in-evacuated-jar experiment, commonly explained by saying that sound is not transmitted through a "vacuum"; waves will still travel without abnormal dissipation in gases at low pressure. The principal difficulty is to get the wave into the gas in the first place.

10. Beams.—A relatively sharp beam can be produced from a light source with mirrors and lenses. Common experience indicates that most ordinary audible sources radiate in all directions. This is particularly noticeable in the human voice. However, ultrasonic (inaudible) sources can produce beam radiation. Qualitatively, consider a plane sound wave traveling in the x direction and striking the infinite rigid baffle W placed at right angles to the direction of propagation (fig. 16). Let a hole be cut in the baffle with centre at 0 on the x axis, so that some of the wave can go through. By Huygens' principle the sound field to the right of the barrier will depend on the wave front at the hole. In other words, every point in the hole will act effectively as an individual source of sound, sending out waves whose superposition at any point (*e.g.*, P) will determine the acoustic intensity there. Calculations of this superposition must consider that the effect of each part of the sound disturbance in the hole at the point P will depend on the distance of this part from P. This is not simply because intensity falls off with distance, but more particularly that wave disturbances reaching P from different parts of the hole can arrive out of phase with each other. Thus if the distances to P from two points of the hole differ by a half wavelength or any odd multiple thereof, two disturbances starting together from these points will be effectively a half wavelength apart on arrival and hence will cancel (interfere destructively with each other). If the two distances differ by a whole number of wavelengths, the disturbances will arrive in phase to give constructive interference; *i.e.*, there will be a reinforcement of the resulting disturbance at P. If the wavelength is small compared with the diameter of the hole, the magnitude of the radiated disturbance will tend to be larger in the right circular cylinder whose axis is the x axis and whose diameter is equal to that of the hole. At points like P' well outside this cylinder the intensity will be decidedly less and grow more so as P' recedes from the axis. This will not follow if the wavelength is large compared with the size of the hole. If it is large enough radiation will tend to spread more or less uniformly in all directions to the right of the baffle; *i.e.*, act effectively as a hemispherical wave. Thus with short wavelength or high-frequency radiation acoustic beams something like beams of light can be formed. Since ultrasonic waves have frequencies much smaller than those of visible light, their beams are by no means so sharp as light beams.

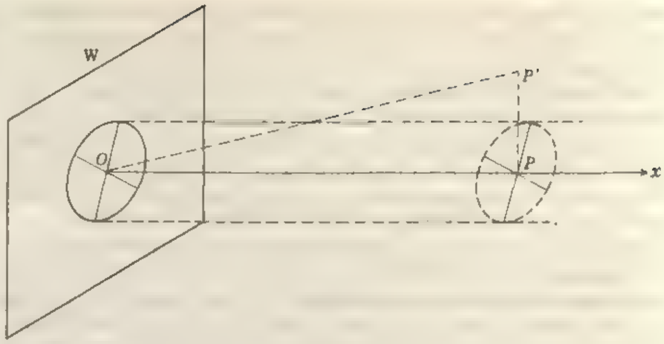

FIG. 16

Such considerations also hold if the hole is filled with a vibrating piston source. If the amplitude of the velocity at each point of the piston has the constant value ξ_0, and the wavelength λ and radius a of the piston are connected by the relation $a = m\lambda$ (where m is any number), the intensity I at any point P on the x axis distant x from the piston is given by

$$I = 2\rho_0 c\xi_0^2 \sin^2(\pi m^2\lambda/2x) \qquad (134)$$

Thus the intensity on the axis runs through a succession of maxima and minima over the region for which $m^2\lambda > x > m\lambda$. However, when $x > m^2\lambda$, I effectively falls off inversely as the square of the distance. This shows that no matter what the wavelength is, cylindrical beam radiation will not persist indefinitely far from the source; instead, there will be conical divergence after $x = m^2\lambda$. The order of magnitude of the conical or solid angle in this case is π/m^2. More exactly, for x twice the effective diameter of the piston the circle at the periphery of which the intensity falls to 1/10 that at the axis in the same plane will subtend at the centre of the source a solid angle corresponding to a plane angular spread of 2 arc tan (.45λ/a). Thus for a piston source with $a = 10$ cm. emitting radiation of frequency 50 kc. the plane angular spread of the beam is about 15°.

An interesting special case is that of a concave piston with

radial motion of its parts. Here there exists the possibility of getting focused radiation with consequent increased intensity at some points.

11. Practical Sources.—*Voice and Speech.*—The human voice operates by forcing air from the trachea to vibrate the vocal cords. This in turn sets into vibration the air in the cavities of the throat and mouth and the resulting disturbance emerges from the lips. The part the vocal cords play in singing and speaking has been established by motion pictures of their vibration (*see* VOICE).

Work on the acoustical power output of conversational speech (for example, that by H. Fletcher) showed that in the case of an average speaker the overall level directly in front of the mouth can vary from 81 db. at 15 cm. from the mouth to 65 db. at 100 cm. These decibel levels are relative to a standard reference level of 10^{-16} w/cm^2. The mouth is not precisely a point source giving rise to spherical waves, for at 100 cm. directly back of the head the intensity in the case mentioned was 62 db. This effect is due to diffraction by the head and is present to some extent in all sound sources that have appreciable size.

The power in speech sound waves varies, being much larger for vowels than for consonants. Ordinary speech involves the superposition of many waves of different frequencies. Moreover, the recognition of speech as mediated by the ear is not at all as simple as the detection of ordinary sound sources by suitable receivers. In the 1960s acoustical studies of speech were directed toward improved methods of analysis (especially of vowels and consonants). Machine synthesis and recognition of speech (*e.g.*, a typewriter that would take spoken dictation) were under development for practical application.

Sirens.—One of the simplest sources of intense sound is the siren, which in principle consists of a disk containing a number of small holes placed at regular intervals around the same periphery. If this is rotated past an orifice lined up with the holes and compressed air is driven through the orifice, the result will be a succession of puffs of air. If the number of puffs per second (governed by the speed of rotation of the disk) is sufficiently large the result will be a periodic sound wave whose frequency is equal to the number of puffs per second. By varying the rotational speed of the disk, variations in frequency can be produced. Sirens have been built to produce both sinusoidal and nonsinusoidal output. In one type of siren acoustic power output as high as 176 w. with an air pressure of 0.2 atm. has been achieved in the frequency range from 3 to 19 kc. (about 150 db. relative to the minimum audible level at 3 kc. at a distance from the siren of 25 cm. on its axis). With air pressure at 2 atm., a power output of 2,000 w. is feasible with an overall efficiency of 20%.

Jet-Edge Tones and Organ Pipes.—Another standard sound source operated by blown air is the jet-edge system coupled to an air column as in the organ pipe. In the familiar type of pipe a narrow jet of air impinges on a narrow edge of the bottom of the pipe. The resulting vibrations are coupled to those of the air in the pipe. The frequency of the wave emitted depends on the velocity of efflux of the air. The natural frequency of the edge tone uncoupled to the pipe increases about linearly with the velocity, but the coupling forces the fundamental tone of the pipe on the system for small velocities. When flow velocity reaches the value for an isolated edge tone of frequency equal to the second harmonic of the pipe, the emitted tone rises to this harmonic and the pipe is said to be overblown. The theory of edge tones was uncertain in the 1960s, though their production is clearly associated with turbulence (vortex motion) in the air flow in the vicinity of the edge.

Closely allied to the jet edge is the Hartmann oscillator in which a high-velocity jet is directed at the orifice of a small bottle-shaped resonator. Usually the output is mainly ultrasonic radiation of high intensity.

Electroacoustic Sources.—The most important sound sources in practical use employ electrical energy. These may be divided into two main classes: irreversible and reversible. In irreversible sources the energy for sound radiation is supplied by a flow of fluid (air or water) under pressure, and the electrical energy is used for control. For example, a variable magnetic field can produce vibrations in a reed or diaphragm that will control the flow of compressed air through variable orifices. Such a device can produce very intense sound waves with high efficiency (*i.e.*, high acoustic energy output relative to the electrical and mechanical input). In this respect it resembles the siren, though it is not a single-frequency source.

A reversible electroacoustic source transforms electrical energy directly into mechanical energy and thence into acoustical radiation. As its name implies, it can function in reverse to transform acoustical into electrical energy via some mechanical structure. Such sources can therefore be used equally well as receivers. What is called the reciprocal or reciprocity theorem (*see* section II.14 above) states that under specified conditions a good reversible source of sound will be a good receiver. It was shown by W. Schottky that the ratio of the reception efficiency to the emission efficiency decreases with the square of the frequency. This means that low frequencies are relatively better received than emitted.

Any system that transforms electrical to acoustical energy is called an electroacoustic transducer, whether used for emission or reception. The important characteristics of a transducer used as a source are its acoustical output, its efficiency, and its departure from linearity. This departure is the extent to which the mechanical force producing the vibrations is not strictly proportional to the electrical field or voltage applied in the input. Such nonlinearity (lack of proportionality) leads to distortion in the radiated output. Another characteristic that is often significant is the directivity; that is, the intensity of the radiation in different directions from the source.

Electroacoustic transducers develop an oscillating force operating on a mechanical vibrator; *i.e.*, a rod or diaphragm. In the electromagnetic transducer, an alternating current of the frequency desired for the acoustic output is passed through a coil that actuates an electromagnet to produce an alternating force on a diaphragm of iron or some magnetic alloy. This is the type employed in the usual telephone. In the more common electrodynamic transducer, the oscillating current passes through a coil suspended in a permanent magnetic field and undergoes the usual ponderomotive force. The coil (called the voice coil) is fastened mechanically to the radiating surface. In the well-known loud-speaker (*q.v.*) the latter is usually a cone attached to the voice coil at or near its vertex. The cone is the acoustical element, radiating directly to the surrounding medium. In earlier types the conical diaphragm was coupled to the air by means of a flaring horn, a method that continues to be used in large speakers for auditorium use. Mounting the cone on a baffle or in a cabinet can also improve its radiating efficiency. The cone is a resonant system; this can lead to distorted output at certain frequencies unless mechanical or electrical filters are employed. Compromises can be made in the size of the conical diaphragm. If it is small, the number of resonance frequencies in the audible range is small; but it takes more power to drive it for a desired output because of the small radiating surface. A larger cone is a more efficient radiator, although it has more resonance frequencies. If the latter are numerous enough they may be distributed over the usable frequency range to give good reproduction. All the general properties of acoustic radiators discussed in section III.9 above apply here. The efficiency of a dynamic loud-speaker tends to vary directly as its linear dimensions. For speakers in common use (as in radio and television sets) the efficiency runs from 2 to 5%. By the use of horns this can be increased to as much as 50%; these figures are dependent on the frequency range. In a typical small cone speaker 10 cm. in radius the efficiency is 2% only over the frequency range from 75 to 1,000 cycles per second. At 10,000 cycles per second its efficiency has dropped practically to zero.

The total acoustical power output of a dynamic loud-speaker can have maximum values ranging from 0.5 to 150 w., depending on size and the associated electrical circuit. Driving the speaker at high power risks nonlinear behaviour; *i.e.*, large amplitude diaphragm motion which no longer is proportional to the electrical voltage.

Another kind of reversible electroacoustic transducer is the electrostatic or condenser type. In this an alternating electrostatic

field of high intensity (*i.e.*, many volts per centimetre) is set up between a fixed metal plate and a thin metal diaphragm separated by a very small distance. The diaphragm is set into vibration by alternate attraction to and repulsion from the fixed plate. By proper choice of mounting and dimensions such transducers can give rather uniform output over a wide frequency range. However, their radiation efficiency is low except at very high (ultrasonic) frequencies, and they are more commonly used as receivers (microphones).

For high-frequency radiation the most important electroacoustic radiators employ piezoelectric (sometimes called electrostrictive) and magnetostrictive effects. Some asymmetric crystals like quartz and Rochelle salt generate electrical charges of differing sign on opposite faces when subjected to mechanical stress. This is the piezoelectric effect (*see* further PIEZOELECTRICITY). If such a crystal is made the dielectric in a condenser subjected to an alternating electrical field the crystal will vibrate with the frequency of the field. When a plate of quartz is cut with its faces parallel to the optic axis of the crystal (so-called X cut) the highest fundamental frequency will correspond to vibrations in the direction of its thickness. This frequency is given approximately by the empirical formula

$$\nu = \frac{286}{d} \times 10^3 \qquad (135)$$

in cycles per second, where d is the thickness in centimetres. By making the quartz oscillator thin enough, ultrasonic frequencies may be generated. Moreover, harmonics of the fundamental can provide even higher frequencies, and are often used, since there is a practical lower limit to d. The resonance in a quartz crystal is very sharp.

For ultrasonic radiation usually a number of X-cut crystals are arranged in the form of a mosaic to provide a larger radiating surface. The piezoelectric effect can also be used in a loud-speaker in the audio range. In this case it is customary to cement two or more crystal plates together and arrange the electrodes so that the whole structure will bend or twist when electrically excited. Large amplitudes can be obtained in this way, although the system is not so practicable as the electrodynamic speaker. In the early 1960s the practical upper frequency limit of ultrasonic radiation obtainable from piezoelectric generators was 10^{10} cycles per second (10,000 Mc.). By 1964 this had been raised by applying laser techniques to 6×10^{10} cycles per second.

The magnetostrictive effect is a change in length of a rod of magnetic material (iron, nickel, or ferromagnetic alloy) when the magnetic field to which it is exposed varies in magnitude (*see* MAGNETISM). If an alternating current passes through a coil surrounding such a rod (not yet magnetized), the rod will vibrate lengthwise with a frequency double that of the current; the frequency will equal that of the current if the rod is already magnetized. If the frequency of the current coincides with one of the resonant modes of the rod, particularly large vibrations result and sound waves of this frequency are radiated. As an example, a nickel rod 10 cm. long emits a fundamental frequency of 24.3 kc. Magnetostrictive sources are less efficient than piezoelectric devices largely because of the loss of energy through hysteresis in the magnetized rod. This can be reduced by using as a sender laminated nickel sheets fastened together as in the core of a transformer. Such transducers are used in producing underwater acoustic beams, usually beyond the audible range.

12. Doppler Effect.—In the discussion of sound sources it has been tacitly assumed that the source is at rest relative to the medium. However, moving sources are important in application; *e.g.*, airplanes, submarines, and projectiles. A significant effect of such motion on acoustic reception is the perceived change in pitch, in accordance with the Doppler principle. If a harmonic source of frequency ν moves with linear velocity v_s in a stationary medium, and a receiver is moving with velocity v_r along the same line, the receiver will estimate the frequency as ν' where

$$\nu' = \nu(c - v_r)/(c - v_s) \qquad (136)$$

where c is the acoustic velocity. Here v_r and v_s are reckoned as positive in the direction from the source to the receiver and negative otherwise. For the special case of a receiver at rest and the source in motion, the apparent frequency at the receiver is lower than the frequency if the source is receding, and is higher than the source frequency if the source is approaching. Knowledge of ν and measurement of ν' thus permit the determination of the velocity of the source, a matter of significance in military applications.

IV. ACOUSTIC RECEPTION

1. Introduction.—To be studied and applied, acoustic energy must be detected; *i.e.*, transformed to make it perceptible to people or sensible to cybernetic devices. This is the function of a sound receiver; any scheme for transforming the energy of elastic deformation of a medium can serve the purpose. Every reversible sound source can in principle be used as a sound receiver.

2. The Ear and Hearing.—Normal people can detect acoustic intensity as low as 10^{-16} w/cm², and can stand intensities up to about 10^{-4} w/cm² before pain ensues. The empirical values depend on the frequency, and those cited represent minima and maxima over the range of audibility: approximately 16 to 20,000 cycles per second. The presence of two ears leads to the binaural effect that serves to detect the direction of a distant acoustic source.

The detailed account in EAR, ANATOMY OF, describes the external ear (auricle). The effect of the auricle in gathering sound waves is negligible for most audible frequencies and becomes noticeable only for frequencies higher than 10 kc.

Sound waves set the eardrum (tympanic membrane) into vibration, and this motion is communicated via the bony ossicles (a kind of solid acoustic filter) to the oval window of the cochlea, a spiral cavity. The flexible basilar membrane in the cochlea can vibrate under the impact of motions of the cochlear fluid. Fine hairs in the adjacent organ of Corti in the cochlea communicate these vibrations to terminals of the auditory nerve. The system functions as a transducer, converting mechanical energy to neural energy.

The theory of hearing offered by Helmholtz was that the fibres of the basilar membrane act like resonators tuned to various frequencies over the audible range. Experimental stimulation of the nerve endings in the basilar membrane produces electrical impulses of the same frequency as the exciting sound radiation. These travel along the auditory nerve to the brain, which mediates the auditory experience. In the Helmholtz place theory of hearing, the sound impulse is transformed into a space pattern in the basilar membrane and the neural impulses from the stimulated parts of the membrane tell the brain, so to speak, what the sound is like. In what is called the frequency theory it is assumed that the temporal sequence of disturbance in the radiation is communicated directly to the brain as if the basilar membrane as a whole acted as an electroacoustic transducer. Evidence seems to favour a combination of these points of view (*see* further HEARING).

The thresholds of hearing and feeling as a function of frequency (fig. 17) are based on the original work of H. Fletcher and confirmed by other investigators. The lower curves indicate close

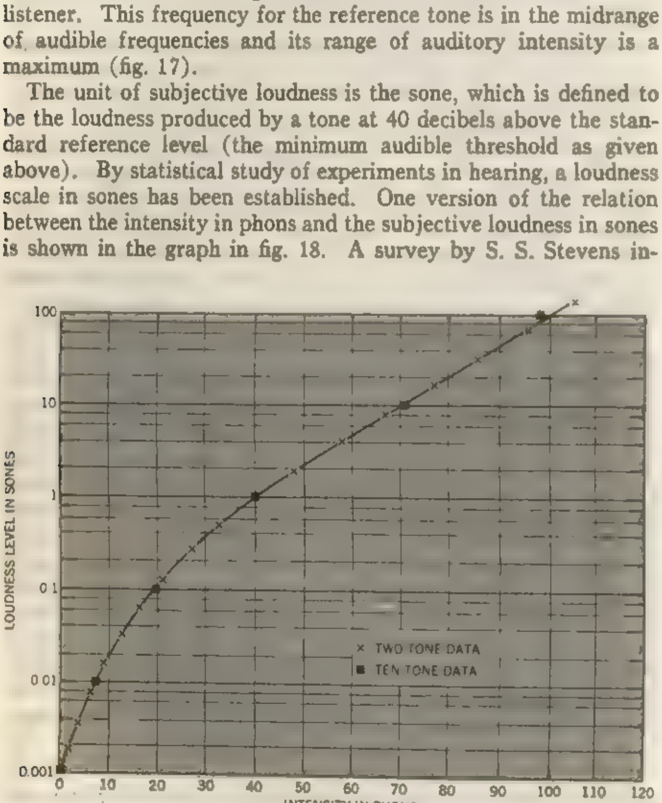
FIG. 17.—AUDITORY AREA BETWEEN THRESHOLDS OF FEELING AND HEARING

agreement between different investigators in relating frequency to minimum audible intensity. This rises at the ends of the audible range and has a minimum at about 3,000 cycles per second. The upper curve is the corresponding plot of the threshold of feeling; intensities greater than those along this curve produce pain. The total audible range is therefore that included between the curves for loudness and feeling. People show considerable variation in thresholds, and the curves represent averages. Advance in age results in general in hearing loss, which would appear in fig. 17 as a rise in the lower curve, though its shape remains roughly the same. The tendency is for the upper frequency limit to drop.

Loudness is an experience that is related to the intensity of the sound wave, but not directly proportional to it. While intensity is an objective physical quantity, loudness is subjective and is defined in terms of the so-called average listener. In one common method of measuring loudness a reference tone of variable intensity is adjusted until it appears to the listener to be as loud as the sound stimulus under test. The number of decibels by which the reference tone has been raised above the minimum audible threshold is said to be the intensity in phons. This applies, strictly speaking, only if the reference tone has the frequency 1,000 cycles/sec and is at a distance greater than 1 m. from the head of the listener. This frequency for the reference tone is in the midrange of audible frequencies and its range of auditory intensity is a maximum (fig. 17).

The unit of subjective loudness is the sone, which is defined to be the loudness produced by a tone at 40 decibels above the standard reference level (the minimum audible threshold as given above). By statistical study of experiments in hearing, a loudness scale in sones has been established. One version of the relation between the intensity in phons and the subjective loudness in sones is shown in the graph in fig. 18. A survey by S. S. Stevens in-



FROM "SPEECH AND HEARING IN COMMUNICATION" BY HARVEY FLETCHER. COPYRIGHT D. VAN NOSTRAND COMPANY, INC., 1953

FIG. 18.—RELATION BETWEEN LOUDNESS LEVEL (INTENSITY) IN PHONS AND SUBJECTIVE LOUDNESS LEVEL IN SONES

dicated the following relation between the loudness L (in sones), and intensity P (in phons)

$$\log_{10} L = 0.03P - k \tag{137}$$

where k is a constant depending on the frequency. For a reference tone of 1,000 cycles/sec, $k = 1.2$. This means that L is proportional to the intensity raised to the power 0.3.

Hearing with two ears leads to the ability to detect the direction of sound waves. Thus a source of sound on the right of the plane bisecting the line joining the ears and perpendicular to it will be recognized as on the right. It was once believed that this arose from the difference in intensity at the two ears, but this theory proved inadequate. Rather, this binaural effect arises from a difference in phase at the two ears. This effect has proved useful in acoustic detectors for gun ranging and underwater ranging.

Since the eardrum is an asymmetrical vibrator (*i.e.*, its displacement for given applied pressure is not the same in the positive as in the negative direction), people can hear summation and difference tones. If two tones of frequencies ν_1 and ν_2 are presented to the ear and if $\nu_1 - \nu_2$ is small compared with either frequency, the usual phenomenon of beats ensues; *i.e.*, the intensity of the perceived sound fluctuates $\nu_1 - \nu_2$ times a second. On the other hand, if ν_1 and ν_2 are widely different a new tone of frequency $\nu_1 - \nu_2$ will be heard. So will a tone of frequency $\nu_1 + \nu_2$. The difference tone is sometimes called a beat-frequency tone. And indeed, tones of frequency $j\nu_1 \pm k\nu_2$ where j and k are arbitrary small integers, have been detected. These effects are all predicted theoretically.

3. Microphones.—Any physical system that can transform a pressure change at a point in a medium into some other form of disturbance (*e.g.*, electrical or optical) can be used as an acoustic receiver. For example, a sensitive flame, formed by burning gas issuing at high speed from a very small orifice and keeping it just below the point of flaring, was an early form of sound receiver. The flame jumps in response to acoustic waves of rather high frequency. In the Phonodeik of D. C. Miller the incident wave vibrates a fine membrane that communicates its motion to a movable mirror from which a spot of light is reflected (*see* HARMONIC ANALYSIS).

Practically all modern sound receivers are electroacoustic transducers, which when used for reception are known as microphones (sometimes termed hydrophones when used in water). Recall that reversible transducers may be used interchangeably as sources and receivers. When used as a microphone such a transducer transforms pressure changes into alternating electrical currents that can be amplified and visualized on an oscillograph (*q.v.*).

One of the important properties of any microphone is its sensitivity or response—defined as the ratio of the electrical output (usually measured in terms of open-circuit voltage) to the excess acoustic pressure on the microphone. The free-field response is that which refers to the pressure at a definite point in the acoustic field before the microphone is inserted. The term pressure response is sometimes used to refer to the case in which the pressure is that acting directly on the microphone when it is in place. The two responses differ because of acoustic diffraction by the microphone, which serves to distort the acoustic field prevailing before the insertion of the microphone. The response is commonly expressed in decibels relative to some arbitrary reference level, which is often chosen to be 1 v. per dyne/cm^2 excess pressure.

Since the microphone diaphragm has mechanical elements its vibration depends on the frequency of the incident radiation; the same holds for the response. A typical response *v.* frequency curve for the simple carbon microphone used widely in telephony is shown in fig. 19. In this figure zero decibel corresponds to 1 v. per dyne/cm^2. Hence -40 db. means 40 db. in intensity level below 1 v. per dyne/cm^2. Since power is proportional to the square of voltage, the number of decibels corresponding to the voltage ratio e_1/e_2 is $20 \log_{10} e_1/e_2$. Hence -40 db. relative to 1 v. per dyne/cm^2 is 10^{-2} v. per dyne/cm^2. From the figure the response stays

FIG. 19.—RESPONSE FREQUENCY CHARACTERISTIC OF SINGLE-BUTTON CARBON MICROPHONE FOR CONSTANT ACOUSTIC PRESSURE OF ONE BAR IN FREE SPACE. RESISTANCE OF BUTTON = 100 OHMS

near this value from 100 to 1,000 cycles per second. Between 1,000 and 2,000 cycles per second it rises to between −30 and −35 db. and thereafter falls off sharply. The uneven response is due to the various modes of vibration of the microphone diaphragm.

The response discussed here has reference to the normal incidence of a plane acoustic wave. Another important characteristic of a microphone is its directivity pattern. This is the plot of the free-field response at a given frequency as a function of the angle of incidence of the radiation. If a microphone is completely nondirectional, the directivity pattern for every plane will be a circle. On the other hand the ideal pattern for the so-called ribbon microphone has the appearance of fig. 20. In the x or $-x$ direction the response is a maximum, falling to zero or near zero in the y or perpendicular direction.

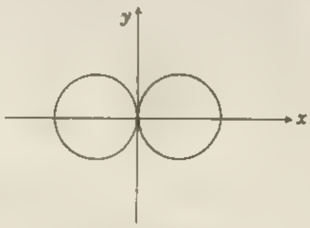

FIG. 20

Electroacoustic microphones may be classed either as pressure or pressure-gradient (velocity) devices. The carbon microphone referred to above is of the pressure type. Another is the condenser microphone, mentioned earlier as the electrostatic or condenser transducer. By appropriate mounting of the condenser diaphragm a response characteristic that is very uniform with frequency can be obtained, though the level is considerably below that of the carbon microphone; for practical use the instrument needs an associated amplifier to increase output voltage. Other examples of the pressure type are crystal microphones and the dynamic or moving-conductor microphone, analogous to the electrodynamic loud-speaker. In the pressure-gradient type of microphone, the electrical voltage produced corresponds to the difference in pressure between two points in the instrument. When this distance is a small fraction of the acoustical wavelength, the pressure gradient corresponds to the particle velocity in the medium. Hence such a device, in which a loosely stretched metallic ribbon is suspended in the air gap between two magnetic pole pieces, may be considered a velocity microphone.

The ribbon vibrates under the influence of the pressure difference produced by the sound wave on its two sides. Its vibration in the magnetic field induces an electromotive force between its two ends. Its response is best at low frequency. Its directivity pattern has been presented in fig. 20, where the x axis is normal to the plane of the ribbon.

Another interesting example of a velocity microphone is the hot-wire variety in which a fine wire is heated electrically. When a sound wave impinges on it the cooling effect alters the electrical resistance in two ways: as a steady change and as an alternating change of twice the frequency of the sound radiation. The sensitivity is materially increased by mounting the wire in the opening of a Helmholtz resonator.

Great increase in the directionality of a microphone may be obtained by mounting it at the focus of a suitably large parabolic reflector.

Waves received by a microphone can be recorded in a variety of ways. The voltage produced can be fed directly into a suitable voltmeter via an amplifier and measured directly in volts or in decibels. Special continuously recording meters have been devised for this purpose. Often it is desirable to reproduce the signal from the microphone in direct visual form and in this case a cathode-ray oscilloscope may be used. This is particularly helpful when the radiation being received is in the form of a succession of pulses. Considerable electronic circuitry is usually employed in modern acoustical reception techniques. By the 1960s the application of semiconductors had led to the construction of transducers (*e.g.*, the transistor microphone) for the detection and measurement of small stresses at acoustic frequencies. *See* also MICROPHONE; TRANSISTOR.

V. APPLICATIONS

1. Measurements.—Acoustical phenomena can be studied in terms of a number of fundamental quantities. These are velocity, frequency, sound pressure (intensity), and impedance. Common methods of measuring these quantities are discussed below.

Velocity.—Velocity in air was the earliest acoustical quantity to be measured. Marin Mersenne is usually credited with making the first estimation (1640) with a pendulum that measured the time between the uttering of a sound and the return of the echo from a distant reflector. He found the value 316 m. per sec.; there is no record of the mean temperature. This is an example of the direct method of velocity measurement, based on the time it takes a sound wave to travel a known distance. Another illustration is the cannon-flash-and-sound method popular in the 17th and 18th centuries. By this method G. A. Borelli and V. Viviani in Florence, Italy (1660), obtained the value of 361 m. per sec.; however, its accuracy is questionable because of individual differences in reaction time among observers. Moreover, velocity in air varies with temperature, chemical composition, wind, and humidity. Automatic time recording was introduced by H. V. Regnault and F. P. Leroux in the 1860s in the course of measuring the velocity in air confined in pipes with rigid walls. This velocity is always somewhat lower than that in the free atmosphere.

The direct method has also been used in liquids and solids. In the 20th century the accepted method employs pulses produced by magnetostriction or by piezoelectric oscillators. For example, a radio-frequency pulse of, say, 6 Mc. per sec. and about 10 microseconds duration excites a quartz crystal. The crystal radiates a corresponding acoustic pulse that strikes a reflector at a distance from the crystal. In the meantime another pulse is emitted by the crystal. If the distance is adjusted so that the first echo coincides with this pulse, the time for the first pulse to travel to the reflector and back equals the time between successively emitted pulses. Since the latter time (the pulse-repetition rate) can be accurately measured the velocity is readily determined as the distance traveled by the pulse divided by the time.

In a more elaborate variant of this method the emitted pulse is received at a second crystal placed at a fixed distance from the emitting crystal, and is there reconverted into an electric signal and sent back through an electronic circuit to the oscillator driving the emitting crystal. There it triggers another pulse which repeats the process, driving a succession of pulses around the loop consisting of an electronic path and an acoustic path. Each triggering pulse is counted and the total time for a large number of round trips is measured by an electronic clock. The total time for the given number of pulses to traverse the acoustic path yields the velocity. The delay in traversing the electronic path must be considered, and can be eliminated by having the same train of pulses pass through two acoustic paths of different lengths in the same medium. With a method of this kind velocity measurements in liquids and solids can be carried out to an accuracy of 1 part in 10^5; it is the group velocity that is measured by this method.

Indirect methods of measuring acoustic velocity may use standing waves. If a standing wave vibration mode is set up in a column of gas, liquid, or solid of fixed length the distance between two successive nodes is a half wavelength. Measurement of this quantity and the frequency of the vibration leads at once to the velocity through the product of the wavelength and frequency. The tube developed by A. A. E. E. Kundt (*q.v.*) applies this method to gases. Here the nodes are indicated by piles of fine powder that become arranged in layers when the tube is excited to a particular resonance frequency. In solids the nodes are usually also indicated by patterns made with lycopodium powder.

Another example of the indirect method is provided by the acoustic interferometer. Waves produced usually by a piezoelectric source are radiated continuously into a fluid medium and strike a movable reflector placed accurately parallel to the source. They are then reflected back to the source. As the distance between source and reflector is varied the current in the plate circuit of the oscillator driving the source varies periodically, the period corresponding to changes in the source-reflector distance equal to one-half wavelength. From a knowledge of the oscillator frequency the velocity is then immediately determined. This method is usually limited to liquids and gases. It has been brought to a high degree of accuracy, although probably it is not susceptible of

quite the same precision as the pulse technique. (*See* also INTERFEROMETER.)

An interesting optical technique for measuring acoustic velocity was devised by P. Debye and F. W. Sears, who discovered that a train of plane sound waves progressing through a liquid can act as a diffraction grating for a beam of monochromatic light traveling through the liquid at right angles to the direction of propagation. The distance l between the lines of the acoustic grating is the acoustic wavelength and can be determined by the usual grating formula for the diffraction angle θ of the light:

$$\sin \theta = \pm \lambda_0/2l \tag{138}$$

where λ_0 is the wavelength of the light. The method has been applied to transparent liquids and solids. It can even be applied indirectly to optically opaque solids.

Frequency.—Since harmonic waves are heavily used in practice, the measurement of frequency is of major importance. To do so requires a frequency standard with respect to which any periodic sound wave can be compared.

A common frequency standard is a tuning fork driven by a vacuum-tube circuit. The fork can be calibrated by having it drive a synchronous motor. The latter in turn rotates a stroboscopic disk illuminated by a flashing lamp controlled by a modulated radio signal, as from the station maintained by the National Bureau of Standards in Washington, D.C. The accuracy of the radio signals is estimated as better than 1 part in 10^7. They are modulated to produce acoustic frequencies of 1,440 and 4,000 cycles per second.

In practical cases it is sufficient to compare the sound wave of unknown frequency (assumed to be a pure tone; *i.e.*, of single frequency only) with a calibrated oscillator that can produce any frequency in a given range. The oscillator is set for the approximate frequency of the unknown. From the beats associated with the two waves the unknown can be accurately determined.

Still more precise is the transformation of an unknown acoustic frequency into an equivalent electrical oscillation which is then placed across one pair of plates of a cathode-ray oscilloscope; across the other pair is placed an oscillation of continuously variable frequency. The resulting Lissajous pattern (*see* CURVES, SPECIAL) on the oscilloscope can be adjusted by varying the frequency of the known electrical oscillation. When it becomes an ellipse the two frequencies are equal. The carrier frequency of the usual radio station ordinarily is not so precisely controlled that it can safely be employed to monitor the frequency of electrical oscillators used to drive electroacoustic transducers.

Intensity.—Recall that the intensity of acoustic radiation may be given either in terms of the acoustic excess pressure p_e or the particle velocity $\dot{\xi}$ in the medium. Hence the measurement of either of these quantities suffices to yield the intensity. Properly calibrated pressure or velocity microphones can therefore serve as intensity meters. However, they must be checked against absolute standards. An absolute standard for the determination of particle velocity is the Rayleigh disk, a light circular plate suspended by a fine fibre in the path of the sound radiation, usually in a tube. If the equilibrium position of the disk in the absence of sound waves is such that the normal to its plane makes an angle θ with the axis of the tube, the torque on the disk in the presence of sound waves for which the mean square particle velocity is $\overline{\dot{\xi}^2}$ becomes

$$L = \frac{4}{3}\rho_0 a^3 \overline{\dot{\xi}^2} \sin 2\theta \tag{139}$$

where a is the radius of the disk and ρ_0 is the mean density of the medium. Usually θ is chosen as 45° and the torque, measured by a torsion head on the suspension, suffices to give $\overline{\dot{\xi}^2}$ and hence the intensity in absolute measure.

Among numerous direct attempts to measure acoustic excess pressure may be mentioned the pinhole probe of C. Barus. He found that if a pinhole orifice in the shape of a cone is inserted in an air column at a pressure loop and the other end is connected to one arm of a sensitive manometer, the excess pressure can be measured directly with an optical interferometer.

E. Gerlach devised a sensitive electrical method for measuring acoustic excess pressure. He compensated the pressure on a diaphragm due to an incident sound wave by measurable electrodynamic forces so that the diaphragm remains motionless under the joint action. Since the required electrodynamic effect can be measured very accurately this provides a precise measure of sound pressure.

Sound waves also produce a radiation pressure on any object on which they impinge. This is a steady pressure like that produced by light and other electromagnetic radiation, and has a magnitude directly proportional to the intensity of the radiation. In practice the so-called Rayleigh radiation pressure is distinguished from the Langevin radiation pressure. Suppose the mean equilibrium hydrostatic pressure in a fluid at rest is p_0. If $\overline{p}$ is the time average pressure in this fluid due to the passage of a sound wave, then $\overline{p} - p_0$ is the Rayleigh radiation pressure. For an elastic liquid it is zero, whereas for an ideal gas it becomes $(\gamma + 1)/2 \cdot I/c$, where I is the intensity of the sound, c its velocity, and γ the ratio of the specific heats of the gas. By the Langevin radiation pressure is meant the difference between the average acoustic pressure at a wall or obstacle (whether absorbing or totally reflecting) and that in the medium at rest behind the obstacle. Calculation shows this to be equal to I/c in every case. This is the radiation pressure usually measured experimentally. For example in the balance method of measuring acoustic absorption in liquids, a vertical sound beam impinges on an obstacle attached to one arm of a balance and can be thereby directly "weighed." Differences in radiation pressure at different points in a sound beam yield corresponding differences in acoustic intensity, hence to the decay of intensity with distance, and ultimately to the absorption coefficient.

The absolute measurement of the amplitude of particle displacement under the action of a sound wave would also provide an accurate measure of intensity. E. N. da C. Andrade attempted to do this by observing the motion of smoke particles in an acoustic field. He predicted theoretically the relation between the acoustic motion of the fluid and the corresponding motion of the smoke particle. Acoustic amplitudes can be measured thereby to an accuracy of about 2% up to a frequency of 5 kc.

The reciprocity theorem mentioned earlier can be used in the calibration of a microphone used to measure acoustic pressure. Let A and B be any two points in a homogeneous isotropic medium of very large extent (a so-called free field) and let a transducer T be located at A while a receiving microphone R is placed at B (fig. 21). If an emf E applied to T produces an acoustic excess pressure p_e at R, and if at the same time an acoustic source of strength Q placed at B produces a current I in the transducer at A, the following equation holds (having due regard for consistent units)

FIG. 21

$$E/p_e = Q/I \tag{140}$$

Assuming that the transducer and microphone are identical instruments, the open-circuit sensitivity of this device may be found through equation (140) in current and voltage. This constitutes the calibration of the instrument as an intensity-measuring device. Since it is rare to have identical transducers, three transducers A, B, C are employed in practical calibration. A is used only as a transmitter, B only as a receiver, and C is used once as a transmitter and once as a receiver. Three measurements are performed using the pairs AB, AC, CB (the first named is always the transmitter). By successive application of the reciprocity theorem the sensitivity of each transducer can be determined in terms of electrical quantities.

Impedance.—Usually denoted Z, impedance was defined earlier as the ratio (generally complex) of the acoustic pressure to the acoustic volume current. Its analogy with electrical impedance makes it a useful quantity in acoustical calculations. A knowledge of Z in every part of an acoustical system permits that system to be replaced with an equivalent electrical circuit or transmission line. This is common practice in acoustical engineering. The impedance of any element in an acoustical circuit (*e.g.*, that of a side

tube or orifice in a horn or filter or that of the termination of a tube by acoustical absorbing material) reveals what is practically important about the acoustical behaviour of the element. The electroacoustic analogy commonly is used to relate acoustic excess pressure to emf and acoustic volume current to electric current. It is sometimes advantageous to use the inverse analogy in which excess pressure is taken as electric current and volume current as emf. Introduced by F. A. Firestone the approach has been applied with particular success to magnetostrictive elements.

Strictly speaking, the direct way of measuring Z would be to find the pressure and volume current independently at the same place. This is rarely practical, nor is it necessary. In most methods theoretical expressions are used that give the impedance at a point in the medium (that is, at some acoustical absorbing material) in terms of the pressure in phase and magnitude at other points. This is standard practice in the so-called transmission-line method to measure the impedance of material placed at the end of a long tube or that of a branch line inserted at a point in the side of the tube. Often the pressure measurements are those of maximum and minimum values in the standing wave setup in the impedance tube.

2. Recording and Reproduction.—Acoustic recording and reproduction became a major industry dating from Thomas A. Edison's invention of the cylindrical phonograph record (1877). Also, a visible record may be made with an oscilloscope and preserved photographically. The analysis of complex sound waves has been facilitated with such visible forms.

For audible reproduction, three types of recording systems are in common use: mechanical, as in the disk phonograph; optical, as in the sound film; and magnetic, as in the tape or wire recorder. In the mechanical system the record is cut into a rotating disk of wax or foil with a cutting stylus. The stylus is usually driven by electroacoustic coupling with the source being recorded. The record then consists of a spiral groove extending from the circumference of the disk to the centre. In most cases the stylus vibrates transversely to the groove, although in the 1960s some interest continued in the vertically vibrating cutter originally employed in Edison's phonograph.

Standard 78 rpm records have about four grooves per millimetre and the maximum excursion from the average line is about 0.06 mm. The long-playing $33\frac{1}{3}$ rpm microgroove record has about eight grooves to the millimetre with a maximum excursion of 0.035 mm. From a metal reproduction of the original cutting, copies can be made in large numbers on shellac or plastic disks.

For proper audible reproduction, the disk must be rotated at the same speed at which the recording was made and a needle must follow the groove. This needle is part of a pickup that usually transforms mechanical vibrations into electrical oscillations and then back again into mechanical vibrations in a loud-speaker. An important requirement in cutting the original groove and in reproducing from the disk is uniformity of frequency response to avoid distortion. The modern high-fidelity phonographic recording system provides fairly uniform frequency response over the range from 25 to 10,000 cycles per second (*see* PHONOGRAPH).

Optical systems of recording modulate a beam of light by means of the sound waves. A photographic record of the light then constitutes the sound track—the basic plan used in sound motion pictures. The sound waves may modulate the brightness of the light source (rarely used) or control the beam electromechanically by a chopper. The sound track may be either of variable density or variable area. In sound movies it is usually placed directly on the film. The sound track passes a beam of light that next falls on a photocell connected through an amplifier to a loud-speaker (*see* MOTION PICTURES).

In magnetic recording a steel wire or film strip coated with iron oxide is moved past an electromagnet (the so-called sound head) through which microphone output is passed. The current through the head magnetizes the wire or tape and provides a more or less permanent record. For reproduction the tape is passed by another sound head in which it induces a variable current that is amplified and fed into a loud-speaker. The record on the wire or tape can be readily "erased" by using a larger demagnetizing field. Much used in commercial broadcasting and in many industrial operations (*e.g.*, to record data from high-speed computers), the magnetic tape system was beginning to compete with the ordinary phonograph in the 1960s for home reproduction (*see* further TAPE RECORDING, MAGNETIC).

Consideration of direction is important in achieving realistic reproduction from a spatially distributed source (*e.g.*, a large orchestra). This is the aim of stereophonic reproduction; for example, microphones spaced at suitable intervals each activate a separate loudspeaker correspondingly spaced in the listening room. In reproduction the sound track from each microphone is played back through a separate loudspeaker.

3. Architectural.—Architectural acoustics is concerned with closed spaces such as lecture halls, theatres, church auditoriums, classrooms, and homes. About 1895 W. C. Sabine studied reverberation time (that is, the time a sound impulse in a room takes to be reduced to one-millionth of its initial intensity). He discovered the relation of this quantity to the volume of the room and the absorbing power of its surfaces; modern architectural acoustics dates from this work.

Acoustic Requirements.—A primary requirement in a living room is that it be free of noise that masks conversation. In a lecture hall speech should be heard clearly in every seat. In a concert hall devoted to instrumental music the listener wants to hear the contribution of the individual instruments. There should be no marked inequalities in reception from one seat to another. Each room, depending on its acoustic use, has an optimum reverberation time; each must be treated to control the normal modes of sound vibration associated with its geometrical shape. Except for some rooms of unusual and complicated shape, the acoustical design of most buildings can be reliably carried out before construction. Concert halls tend to give more difficulty than do rooms used for speakers because of the subtleties involved in aesthetic appreciation (*see* ACOUSTICS OF BUILDINGS).

Acoustic Distribution.—Mathematically, the distribution of sound waves in a closed space involves the solution of equation (6) subject to boundary conditions. This is unfeasible in closed form for any but very simple geometrical shapes. However, the sound source will excite the normal modes of the geometrical space in question in exactly the same way that blowing excites them in an organ pipe.

A room (with three dimensions) has more modes than a linear system like a pipe or finite string, or a two-dimensional vibrator like a membrane. The simplest case is a rectangular enclosure with sides l_1, l_2, l_3. The characteristic frequencies or normal modes are then given by

$$\nu_n = \frac{c}{2}\sqrt{(n_1/l_1)^2 + (n_2/l_2)^2 + (n_3/l_3)^2} \tag{141}$$

where c is the acoustic velocity as usual and n_1, n_2, n_3 are any integers. The modes of lowest frequency correspond to small values of n_1, n_2, n_3. There are no harmonics in the sense of the vibrating string or organ pipe. Between any two frequencies the number of modes increases with average frequency; as a square function if the frequency is high enough.

After the sound source in the room is turned on, all the normal modes will be excited, but eventually only those with frequencies equal to those of the source will persist. The process is complicated by interference between the waves reflected from the room surfaces (producing the normal modes) and the waves emitted from the source. Absorption at the room surfaces limits the buildup of acoustic energy. If reflection from the surfaces were complete, the energy in the resonant modes would increase indefinitely. To make the problem simpler geometrical acoustics is usually employed, and it is assumed that all ray directions are equally probable, so that acoustic diffusion in the room is perfect. Then it can be shown that the root-mean-square excess acoustic pressure p_{ave} in the room in dynes/cm^2 as a function of the time t from the turning on of the source is

$$p_{ave} = 1{,}300\,(W/a)^{1/2}(1 - e^{-cat/4V})^{1/2} \tag{142}$$

where W is the acoustical power output of the source in watts, V is the volume of the room in cubic feet, c is velocity in feet per

second, and a is total surface absorption in square-foot units. If the fractional amount α is absorbed per unit of time, then α is called the absorption coefficient of the surface. Thus if 30% of the incident sound energy is reflected back into the room, the absorption coefficient of the surface is 0.7. Each square foot thus acts as the equivalent of 0.7 sq.ft. of a perfect absorber. It is customary to use the sabin (after W. C. Sabine) as the unit of acoustic absorption at a surface. One sabin is the equivalent of one square foot of perfectly absorbing material. When α is known for each element dS of surface of the room, the total absorption is given by

$$a = \int \alpha \, dS \tag{143}$$

in sabins or square-foot units, where the integral is taken over all the surfaces of the room. It is customary in practical calculations to replace the integral by the sum of products

$$a = \sum \alpha_i S_i \tag{144}$$

where α_i is the average absorption coefficient over the surface S_i, and the sum is taken over all surfaces of the room.

According to equation (142) the average sound pressure in the room continues to grow for an infinite time, approaching the steady-state value

$$p = 1{,}300\,(W/a)^{1/2} \tag{145}$$

For most rooms encountered in practice $ca/4V$ is considerably greater than one sec.$^{-1}$ (*e.g.*, for a cubical room of side l, $ca/4V = 3\bar{\alpha}c/l$, where $\bar{\alpha}$ is the average absorption coefficient) and hence the steady state is effectively attained in a few seconds (unless the room is very large and absorption is very low, as in a cathedral). The pressure in equation (145) is normally expressed in terms of the number of decibels for the equivalent intensity above that corresponding to the standard (average minimum audible) 2×10^{-4} dynes/cm.^{2} This level in decibels above minimum audible then becomes

$$L = 10 \log_{10} (W/a) + 136 \tag{146}$$

The same kind of analysis that leads to equation (142) indicates that if the sound source is stopped when the effective steady state has been reached, the average pressure will decay in accordance with

$$p = 1{,}300\,(W/a)^{1/2} e^{-cat/8V} \tag{147}$$

The time for the pressure to drop to $\frac{1}{1{,}000}$ of its initial value (or 60 db. equivalent drop in intensity) is defined to be the reverberation time of the room. From equation (147) this becomes

$$T = 0.161\, V/a \tag{148}$$

if V is in cubic metres and a is in equivalent square metres of absorption. If V is in cubic feet and a in sabins the corresponding result is

$$T = 0.049\, V/a \tag{149}$$

The two preceding formulas contain Sabine's law of reverberation time, first established on experimental grounds. Actually this law is not completely accurate, particularly for rooms with abnormally high absorption (what are called dead rooms). By considering multiple reflections at the walls more carefully, C. F. Eyring showed that a more accurate expression for the reverberation time is (using feet for dimensions)

$$T = \frac{0.05\, V}{-2.30\, S \log_{10}(1 - \bar{\alpha})} \tag{150}$$

where S is the total surface area of the room and $\bar{\alpha}$ is the average absorption coefficient. If $\bar{\alpha} < < 1$, the expansion of the logarithm gives equation (149) as the first approximation. However, if $\bar{\alpha} > 0.5$, as in a dead room (*e.g.*, a broadcasting studio), equation (150) is a better representation of the facts. It has a definite economic value since it requires much less absorbing material to make a room of specified reverberation time than would be calculated by Sabine's formula.

Both reverberation formulas depend on the assumption of uniform diffusion in the room. However, if complete diffusion were realized there would be no average fluctuation of intensity with frequency at any point, and a measure of diffusion was sought in the quantity

$$\psi = \frac{\Sigma p_{\max} - \Sigma p_{\min}}{n \Delta\nu} \tag{151}$$

where $\Sigma p_{\max}$ is the sum of the pressure maxima in the frequency interval $\Delta\nu$, presumably covering the frequency range of greatest interest in the room in question; $\Sigma p_{\min}$ denotes the sum of the corresponding pressure minima. The n is the number of pressure maxima in the frequency interval.

When diffusing surfaces in the form of wall irregularities (like cylindrical bosses or straight wall sections meeting at obtuse angles close to 180°) are introduced into the room (leading to a subjective impression of better diffusion) the quantity ψ becomes smaller. It therefore seems likely that ψ may be used as a criterion of diffusion; it has been called the diffusity of the room.

Optimum Conditions.—The optimum acoustical conditions in a room depend considerably on its use. If a room is used mainly for speaking a relatively short reverberation time tends to ensure good articulation. With long reverberation successive utterances overlap unless the speech is abnormally slow.

In a standard articulation test the percentage of meaningless monosyllables produced by a speaker that are written correctly (suitably averaged over the room and preferably by several observers) is called the percentage articulation. This simple measure has proved very useful.

Empirically, if the articulation is 85%, an average of about 97% of normal speech will be understood. If the articulation falls to 75%, about 6% of ordinary speech will be misunderstood; these are relatively good conditions, though attentive listening is required. If the articulation drops to 65%, hearing conditions are bad, with nearly 10% of all speech being missed.

Experiments in auditoriums that have a volume of the order of 2×10^5 to 5×10^5 cu.ft. indicate a maximum reverberation time of about 2.5 sec. for satisfactory articulation; best listening conditions would be at about 1 sec. These figures are somewhat idealized since they assume a low general noise level (*i.e.*, about 30 db. above minimum audible) and good sound diffusion. In very large rooms (10^6 cu.ft. and more) no speaker can be heard well without a public-address system no matter how low the reverberation time. A room used primarily for music requires a longer reverberation time than does one used for speech. For an auditorium of volume between 2×10^5 and 5×10^5 cu.ft., music usually requires an optimum reverberation time of about 1.7 sec.; for organ music it is closer to 2 sec. These figures are for a frequency of about 500 cycles per second. The Sabine law indicates that, since absorption a tends to increase with frequency up to about 1,000 cycles per second, the reverberation time varies inversely. Most reverberation times are given for 500 cycles per second; for lower frequencies they will tend to be higher and for higher frequencies slightly lower (though often not appreciably so).

Experiments indicate that surface reflections that reach an auditor within the first 0.05 sec. after the wave coming directly from the source keep the sound from appearing too directional and not sufficiently mixed. They also give the impression of greater loudness. Places in a room where such reflections reach an auditor seem to be preferred; the reason for this was not fully understood in the 1960s. Of course reflected waves arriving too long after the direct stimulus produce unpleasant echoes and should be avoided.

Absorbing Materials.—Since acoustic absorption is the primary factor controlling reverberation time, numerous porous materials are in use. These include cork products, textiles, and materials manufactured with perforations or fissures. Theoretical studies show that a hard smooth surface is a poor absorber compared with one that has many indentations and air pores.

Amplification Systems.—Even a room designed carefully for good acoustics may need artificial amplification if it is very large (or if articulation must be uniformly good, as in a theatre). Amplification systems consist of one or more microphones, appropriate electronic amplifiers, and loudspeakers. In a single-channel

system all microphones, though spread over the source area (*e.g.*, the stage of a theatre), feed the same amplifier for all loudspeakers (placed so that their output seems to originate at the source). For rooms with a volume V of 5×10^4 to 5×10^5 cu.ft. the total acoustical power output in watts for satisfactory reproduction of speech is about $V \times 10^{-7}$.

In a multichannel or stereophonic system each microphone feeds its own loudspeaker. When properly installed the system can, for example, make stimuli from the left side of a stage appear to be coming from that direction.

4. Musical.—In the past, the sounding pitch associated with the various note names has varied greatly; but until relatively recent times acoustical theory as developed by physicists had relatively little influence in such matters. For example, a conference of physicists in Stuttgart, Ger., in 1834 proposed that the musical note A be standardized at 440 cycles per second, yet great variety in practice continued; not until 1938 was this standard adopted internationally. Undoubtedly the advent of large-scale radio broadcasting hastened this move.

Musical instruments are complicated examples of coupled vibrating systems (*i.e.*, systems of many degrees of freedom). They function as acoustical filters, emitting only certain frequencies or combinations thereof (*see* MUSICAL INSTRUMENTS).

Organ pipes and horns are special cases of vibrating air columns. The behaviour of a horn is largely a function of its resonance frequencies; the flare (or bell, as in a trumpet) improves the acoustic impedance match with the surrounding air to yield more radiation than does an equally long tube of uniform cross section (*see* WIND INSTRUMENTS).

The musical possibilities of electrophonic instruments are illustrated by the Theremin, essentially a beat-frequency oscillator connected to a loudspeaker through an amplifier. The capacity controlling the frequency is alterable by the motion of the hand (or a baton) relative to a metal loop. A continuous range of single frequencies is thus available. More elaborate is the Novachord or Hammond organ, a keyboard instrument in which each key controls a rotating wheel that electromagnetically induces a current pulse in a coil. The pulses are mixed, amplified, and fed to a loudspeaker. A similar type of instrument employs variation in electrostatic capacity produced by a series of rotating disks tied in with the grid circuits of a set of vacuum tubes. Another example is the photoelectric organ, in which light from a source of controllable intensity falls on the edge of a rotating disk bearing a sinusoidal pattern in black paint. After being chopped by the disk the light falls on a photocell and the resulting current after amplification is fed to a loudspeaker (*see* ELECTRONIC MUSIC).

5. Military.—Many military acoustical applications have been subject to security classification, but the basic ideas have been published. Technical problems arising in these applications stimulated fundamental research; *e.g.*, inquiries into the nature of abnormal acoustic absorption in liquids.

The principal military use of acoustics has been in the detection of objects at a distance in the atmosphere and under water.

Ranging in Air.—If an impulsive sound wave from a source at O (fig. 22) is received at microphones placed at A and B, knowledge of the acoustic velocity and the differences in time of arrival at the two microphones is sufficient to establish the direction of the source. For if C is midway between A and B on the base line of the microphones

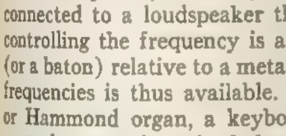

FIG. 22

$$\cos \theta = c(t_A - t_B)/l \qquad (152)$$

where l is the distance between A and B, t_A and t_B are the arrival times, and c is the acoustic velocity. It is assumed that l is very short compared with either ct_A or ct_B. Another microphone along the same base line provides a second bearing on the source. The intersection of the two bearings yields the distance of the source from the microphones; this provides in principle a method of artillery ranging. However, the projection of a shell from a gun involves the explosive discharge of the gun; the bow wave from the projectile which comes as a sharp crack; and the sound wave from the bursting of the shell. Successful ranging of the gun requires that the microphone distinguish these three; hot-wire and condenser microphones with resonance in the region of low frequencies are employed for the purpose. Since acoustic velocity is dependent on wind, temperature, and humidity concomitant meteorological measurements are required. Errors in location are reduced if more than three microphones are employed on a longer base line.

Detection of airplanes with large horns using the binaural effect was practised with some success in World War I, but abandoned in favour of electromagnetic wave methods in World War II (*see* RADAR).

Underwater Detection.—Acoustics has been extensively applied to the detection of underwater objects like submarines. Electromagnetic radiation is too rapidly damped (sea water being a good conductor of electricity) to be of much use. However, the sea is a good transmitter of sound radiation; since its characteristic impedance is much closer to that of solid sound sources than that of air, it is easier to radiate sound waves into water than into air.

One general method of underwater detection, like sound ranging in air, is based on passive reception of sound waves from an object. The waves from a ship or a submarine come mainly from the cavitation produced in the water by the propellers. Some engine vibration will be transmitted into the water and the hull will itself vibrate as a diaphragm or solid shell. The hull wave is mainly of low frequency, while the cavitation wave will have sonic and ultrasonic components. For localization in passive listening the binaural effect is employed, usually with an array of underwater microphones termed hydrophones. The latter are usually magnetostrictive or piezoelectric. They are connected to an elaborate electronic circuit that permits phase differences of the sound waves at the various hydrophones to be compensated electrically so that the whole array can be "steered" in the direction of the sound source without actually rotating.

To locate an underwater object that may be producing no sound waves, an echo method was devised similar to echo-sounding in which an ultrasonic pulse is emitted straight down from near the surface. Some of the pulse is reflected from the bottom and returns to a receiver at the surface that may be the same transducer as the sender. From the time difference between the direct and reflected pulse and knowledge of acoustic velocity in sea water, the depth may be calculated or read from a specially designed recorder. When used to detect distant objects this method is known as sonar (or asdic in Great Britain). If the emitted pulse is of high frequency, it travels in a more or less narrow beam. By rotation of the transducer this beam sweeps the surrounding medium and a reflected pulse returns from any obstacle to the sender, who can locate the object from bearing and distance. This method is the acoustic analogue of radar. Since the acoustic absorption coefficient in water increases roughly with the square of the frequency, the method fails in long-range detection at high frequency; at very low frequency the beamlike quality is lost unless the source is large. Hence a compromise must be worked out. The pulse is subject to disturbing effects if the water is nonhomogeneous because of variations in temperature, currents, changes in salinity, and so on. The sound beam then suffers refraction, diffraction, and scattering as well as absorption. Corrections must be made if the echo method is to give accurate results. In the 1960s sonar was becoming increasingly important in navigation and undersea exploration (*see* OCEAN AND OCEANOGRAPHY: *Sound in the Sea*).

6. Ultrasonics.—The velocity, attenuation, and scattering of sound waves depend on the physical properties of the medium. Recall the dependence of velocity on elastic moduli and density. Attenuation or absorption in a fluid can depend on viscosity, thermal conductivity, and on internal energy changes in the molecules of the fluid (thermal relaxation). Scattering of sound waves by a suspension depends on the size and distribution of the suspended particles. Thus acoustical measurements can shed light on the properties of the medium. Means are available for producing and detecting high-frequency waves extending far beyond the upper

limit of audibility. This branch of acoustics is known as ultrasonics and has been a principal tool in the study of matter. Just as X rays (ultrahigh-frequency electromagnetic radiation) can tell more about the structure of crystals than can visible light (of lower frequency), so ultrasonic radiation of frequency up to 10,000 Mc. can provide many more details of structure than can audible radiation. Ultrasonic radiation also has valuable applications in technology, chemistry, and medicine (*see* ULTRASONICS).

7. Noise Control.—Noise or unwanted auditory experience was a vital aspect of practical acoustics in the 1960s. Noise control had developed into a major branch of acoustical engineering.

Every advance in the transformation of heat energy into mechanical energy has involved a noise problem, and in general it increases with power production. Large-scale turbulence of exhaust gases from a jet airplane is an unusually intense source of sound. Control of the noise is more difficult than that from an automobile engine in which a relatively simple acoustic filter or muffler is acceptable.

Noise control problems involve the standard acoustical elements: source, transmission path, and receiver. Common noise sources include machinery, some so-called musical instruments, jets, and living things, including people. Transmission may be through the open air, as street noises or airplane racket; through the sea, as acoustic waves from fish that interfere with underwater signaling; through the walls of buildings, and so on. The human ear is a most vulnerable receiver; however, noisy vibration may be enough to damage heavy machinery (*see* VIBRATION CONTROL).

As an example of problems in noise control, consider factory noise, which, if produced by intense and sustained sources, can permanently damage the hearing of a worker. Various methods of control are used (as shown by the work of L. L. Beranek); in one, a partial enclosure may be built around a noisy machine and lined with acoustic absorbing material. This can provide an attenuation of from 5 to 10 db. for a worker on the outside. Full enclosure of the machine can provide perhaps 40 or 50 db. attenuation. But if the worker must function right at the machine, ear defenders (small acoustic filters inserted in the ear canal) may be required (*see* NOISE AND ITS CONTROL).

SOUND, THE (ØRESUND). One of the busiest sea-lanes in the world, the Sound separates Sjælland (Zealand), the largest island of Denmark, from Skåne, the southern tip of Sweden. Its extreme length, between Kullen and Falsterbo on the eastern shore, is 70 mi. (113 km.). The most landlocked portion between Helsingør-Hälsingborg in the north (width 3 mi. [5 km.]) and Copenhagen-Malmö in the south (width 9 mi. [14.5 km.]) is 33 mi. (53 km.) long. In the past, political control of this seaway, the shortest route from the Kattegat to the Baltic, conferred great commercial benefits. Before 1658 Denmark controlled both shores and exacted tolls from all shipping passing through. Even after Skåne was annexed by Sweden in 1658 the great Danish coastal fortress of Kronborg at Helsingør (Elsinore) still levied the Sound toll until 1857. Three large islands lie in the Sound: Amager (partly embraced by Copenhagen), Saltholm, and Ven. Between the two former lies the channel of Drogden, while the broader channel of Flinterenden separates Saltholm from Skåne. The shipping channel has a minimum depth of 23 ft. (7 m.). Ice in the almost tideless strait may impede navigation in severe winters. Copenhagen and Helsingør are the principal ports on the Danish side, Malmö and Hälsingborg on the Swedish side. (HA. T.)

SOUND BARRIER: *see* AERODYNAMICS: *Supersonic Aerodynamics*.

SOUNDING, the act of determining the depth of the ocean or any body of water. The number representing the depth of water at any position is "a sounding"; and a ship is said to be "on soundings" when she is in a portion of the ocean, as over the continental shelves, where bottom is easily reached, and "off soundings" when in deeper water.

Sounding by Pole.—The first Stone Age man who shoved off his crude dugout into a muddy estuary no doubt quickly discovered that he needed a way to determine the depth of water, and he doubtless soon made use of a marked pole which he poked vertically toward the bottom. A sounding pole is shown in an Egyptian carving of 1500 B.C. Although they are still employed in some parts of the world, long poles are dangerous and tiring devices to use from a boat in any but calm waters, and the development of the lead line probably came quite early in the history of navigation.

Sounding by Line.—The lead line essentially is a length of fishing line equipped with a sinker (the sounding lead) and marked at appropriate intervals with knots, coloured tags, or similar indicators. Its use is mentioned by Herodotus (430 B.C.) and in Acts xxvii, 28 ("So they sounded and found twenty fathoms . . ."), and it is still employed under suitable conditions. Formerly the sounding lead was provided with a hollow at the bottom, into which tallow was placed. A lead so fitted was described as "armed," and with it a sample of the bottom could be obtained at the same time as the depth was determined. Since in many areas there is more variation in the type and colour of bottom than there is in depth, the navigator had an additional bit of information to help in ascertaining his position.

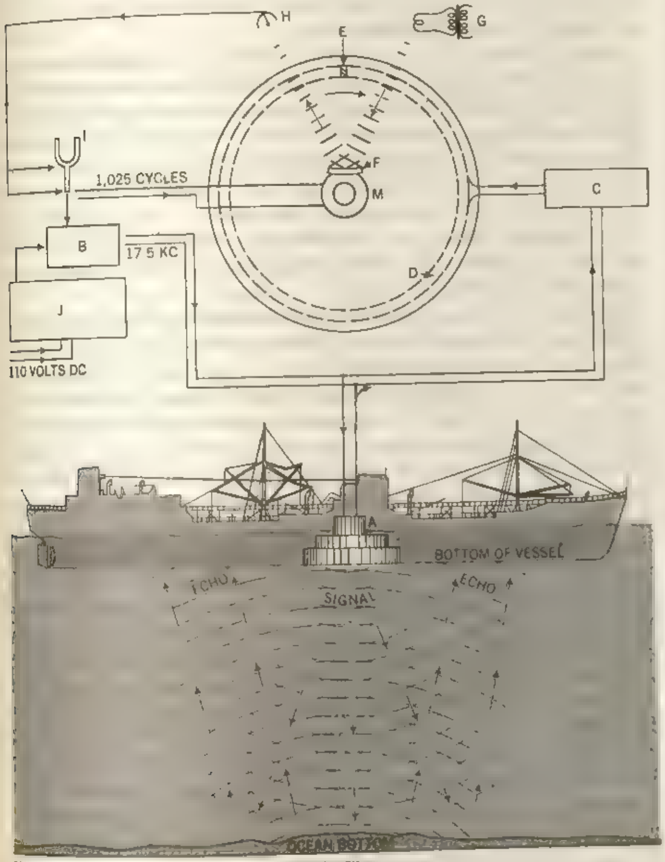
To obtain an accurate sounding the lead line must be vertical; hence the ship must be nearly motionless or else in very shallow water. In order to permit a ship to obtain a sounding while underway, various expedients were tried that measured the depth of water independently of the length of line paid out. One device was a vertically oriented propeller, which rotated as the lead sank to the bottom and thereby actuated a counter. It was difficult to haul this device back in at high speeds, and in unskilled hands it could give erroneous results; nevertheless it was fairly widely used in the 19th century. As steamers came into wide use and the speed and size of vessels increased, investigation of causes of shipwrecks showed more and more cases where soundings had been neglected, the captains preferring to take chances rather than risk delays through slowing or stopping to obtain soundings.

The problem was presented to Sir William Thomson (later Lord Kelvin; *q.v.*), professor of natural philosophy at Glasgow University, in 1878, and his solution received wide use as the Kelvin-White sounding machine. This device consisted of a small hand winch holding a reel of piano wire, which was as strong as the hemp lines previously used and much easier to retrieve. To the sounding lead was attached a glass tube, coated on the inside with silver chromate and sealed at the upper end but open at the lower. As the tube descended in the water, hydrostatic pressure compressed the air and permitted the water to rise. A chemical reaction with the seawater changed red silver chromate to white silver chloride, so that after the tube was hauled back aboard the depth could readily be determined. Thus, if the seawater had come halfway up the tube, the hydrostatic pressure had been two atm., corresponding to a depth of 33 ft.; two-thirds of the way up was three atm. or 66 ft.; and so on. As long as the lead reached

the bottom, a good record of the depth was obtained regardless of the amount of wire that had been paid out.

The Kelvin-White system, with improvements such as the use of power on the winch and stranded wires, was standard on most vessels until after 1930. The echo sounder, which measures the time required for sound waves to return to the ship after being reflected from the bottom, gradually replaced it.

Echo Sounders.—A typical echo sounder, the Dorsey Fathometer, is shown schematically in the figure.



BY COURTESY OF U.S. COAST AND GEODETIC SURVEY

SCHEMATIC DIAGRAM OF DORSEY FATHOMETER

The transceiver A is a combined transmitting and receiving unit, mounted in a hole cut in the bottom of the vessel. It receives a powerful pulse of electrical energy from a 17.5-kc. oscillator and amplifier B and then converts this pulse to an acoustic pressure wave directed downward into the water. The received echo signals in turn are converted from acoustic to electrical energy and then fed to the echo amplifier C, which amplifies the weak voltage and flashes the neon tube D. An aluminum disk rotated at 1,230 r.p.m. by a synchronous motor M hides the neon tube except for a narrow slot E. The motor also rotates a mirror F. Once each revolution the mirror reflects the beam from a light G onto a photocell H, which keys the oscillator B into vibrating for 0.7 milliseconds. Thus, each time the index slot E is vertical, a signal is generated in the oscillator-amplifier B and transmitted into the water by the transceiver A. Assuming that the water is 120 ft. deep, the signal, traveling at 4,800 ft. a second, reaches the bottom in $\frac{1}{40}$ sec., and the echo returns in another $\frac{1}{40}$ sec., or a total of $\frac{1}{20}$ sec. Since the disk rotates at 1,230 r.p.m. or 20.5 r.p.s., the index slot will have completed almost one complete revolution, and the flash of the neon tube will be seen just to the left of the zero mark. In this configuration, the echo sounder has a scale range of 120 ft. (20 fathoms), but deeper ranges can be provided by driving index disks through suitable reduction gears. Since the accuracy of the depth determination depends entirely on accuracy of timing the revolutions, a tuning fork I is provided to regulate the frequency of the power supply. A converter J produces alternating current from the ship's direct current supply.

Numerous modifications of the echo sounder have been made. The Fathometer in the figure uses ultrasonic frequencies; others use sound in the audible range, which is capable of being transmitted for greater distances in seawater. This Fathometer has a magnetostrictive transmitter, but piezoelectric, electromagnetic or percussion sound sources can be used. For survey purposes it is desirable to have a permanent record of the soundings, and echo sounders are used that draw a continuous profile of the bottom on a roll of paper.

The echo sounder is an aspect of the general underwater navigation system called sonar (*see* NAVIGATION: *Electronic Aids for Marine Use*).

Deep-Sea Sounding.—The sounding methods described above are adequate for the ordinary purposes of navigation "on soundings." Commencing about 1850, with the promotion of submarine cables, there arose an interest in the exact determination of deep oceanic depths, which could be met only by the use of much more elaborate equipment. Devices were developed that released the lead on contact with the bottom, so that the line could be hauled in more readily, while accurate meters measured the amount of wire paid out. Even so, a sounding might require several hours to complete, and although the ship was maneuvered to permit the line to descend vertically as it entered the water, there was the possibility that different currents at depth might cause the line to depart from the vertical. Echo sounding has proved as feasible in deep water as in shoal, when signals of suitable power are sent out. (J. L.)

SOURIS, an important tributary river flowing into the right bank of the Assiniboine River, about 20 mi. SE of Brandon, Man., Can. The river is 600 mi. in length and drains an area of about 22,000 sq.mi. in the provinces of Manitoba and Saskatchewan and the state of North Dakota. Rising in the southern part of the Regina plains near Weyburn, Sask., it receives drainage from Moose Mountain to the east, and the Coteau du Missouri on the west. Flowing southeasterly, it crosses the international boundary into North Dakota, making a long loop before recrossing into Manitoba and turning northeasterly to join the Assiniboine River. A considerable part of the drainage basin is floored by silt and clay deposited on the bottom of an ancient glacial lake known to geologists as Lake Souris. The river follows the valley cut by the outfall from the old lake for some distance near Souris, Man., but suddenly turns northeastward, cutting a deep, narrow valley through the Tiger Hills to join the Assiniboine. The downstream extension of the old valley is drained by the Pembina River. The grassy plains drained by the Souris River were once the grazing grounds of countless buffalo herds. They form an important part of the hard red spring-wheat belt of central North America. Near Estevan and Bienfait, Sask., there is extensive strip mining of lignite coal. Productive oil wells are near Midale, Sask., Virden, Man., and other points. There are coal mines also near Minot, N.D., the largest city on the Souris River. (D. F. Pu.)

SOUSA, JOHN PHILIP (1854–1932), U.S. bandmaster and composer of military marches, called the "March King." Son of a Portuguese father and a German mother, he was born on Nov. 6, 1854, at Washington, D.C., where he studied the violin and harmony with J. Esputa and G. F. Benkert. In 1867 he began to follow the career of his father as trombonist, but later took engagements as an orchestral violinist, playing at Philadelphia under Offenbach in 1877, and as a conductor. He brought the U.S. Marine Band, which he led from 1880 to 1892, to a higher standard of performance, and in September 1892 gave the first concert with his own band with which he toured in the U.S. and Europe (1900–05), and which he eventually took on a world tour (1910–11). Sousa wrote about 140 military marches, remarkable for their rhythmic and instrumental effects, the most celebrated of which is "The Stars and Stripes Forever" (1897). Others are "Semper Fidelis" (1888), "The Washington Post" (1889), and "The Liberty Bell" (1893). Between 1879 and 1915 he wrote 11 operettas, of which the most successful was *El Capitan* (Boston, 1896). During World War I he was adviser to the U.S. government on military music, but later continued his tours. He compiled for the U.S.

Naval Department *National, Patriotic and Typical Airs of All Lands* (1890); and wrote three novels, among them *The Fifth String* (1902), and treatises on the trumpet and violin. He died at Reading, Pa., on March 6, 1932.

See J. P. Sousa, *Marching Along* (1928).

SOUTAR, WILLIAM (1898–1943), Scottish poet, was second in importance only to Hugh Macdiarmid among the writers of the Scottish Renaissance movement. He was born in Perth on April 28, 1898, the son of a master-joiner, and educated at Perth Academy and Edinburgh University. During World War I he served for two years in the navy, where he contracted the osteoarthritis from which he suffered thereafter. From October 1923 he was a semi-invalid, and after the failure of an operation in May 1930 he was bedridden. He was saved from apathy and despair by his delight in the variety of nature, his love of mankind, and his devotion to the craft of letters. His "bairn-rhymes" in Scots, *Seeds in the Wind* (1933), are beast-fables which express a mature insight into the life of things in terms of the "innocent eye" vision of childhood. In *Poems in Scots* (1935) he developed the ballad style toward the objective expression of individual lyricism. During his last ten years his principal output in Scots consisted of "whigmaleeries," humorous poems full of comic exaggeration, interweaving the fantastic and the familiar. He was fond of miniatures, publishing *Riddles in Scots* (1937), while as a poet in English he was at his best in the pointed epigrams of *Brief Words* (1935) and the short nature-lyrics of *The Expectant Silence* (1944). He died in Perth on Oct. 15, 1943, leaving a mass of unpublished verse and prose.

SOUTH, THE, an extensive region covering approximately the southeastern quarter of the United States. There is no clear line of demarcation between it and the North but the Mason and Dixon Line (*q.v.*) and the Ohio River are popularly regarded as dividing the two regions. The South is generally considered to include the states of Virginia, North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, Tennessee, and Arkansas, as well as parts of the states of Texas, Oklahoma, Missouri, Kentucky, West Virginia, Maryland, and Delaware. Since the end of the colonial period the South has formed a major section of the United States, substantially distinct from other sections in agriculture, economic and social structure, and political attitudes.

Geography.—In its physical geography, the South does not possess any natural unity. In fact, it includes a number of quite diverse geographical districts. Along the coast, from Maryland to the Rio Grande, there is a low coastal plain, marked by a series of alluvial rivers flowing eastward to the Atlantic or southward to the Gulf of Mexico. On the Atlantic shore, this coastal plain rises gradually to the "fall line" where the streams cease to be navigable. There begins an area known as the piedmont, where the land is rolling or hilly, erosion has taken place, and reddish-yellow clay soils predominate in contrast to the sandy or alluvial soils of the coast. At its western edge, the piedmont rises into the Appalachian mountain system, the southern part of which extends from Maryland to northern Georgia and Alabama. The easternmost part of this system consists of the Blue Ridge Mountains, behind which lies the main Appalachian ridge. Beyond the Appalachian ridge is the high and mountainous country of the Cumberland Plateau. This mountainous terrain dominates the western parts of Maryland, Virginia, North Carolina, the northern part of Georgia, the eastern parts of Tennessee and Kentucky, and most of West Virginia.

Just as the Appalachian mountain system is the key to the geography of the eastern or Atlantic coastal part of the South, so the Mississippi River Valley is the key to the western or Gulf coastal part. Although portions of Alabama, Mississippi, Louisiana, and Texas drain directly into the Gulf of Mexico, other parts of these states and all of Kentucky, Tennessee, Missouri, and Arkansas drain into the Mississippi. On its west bank, such major rivers as the Missouri, the White, the Arkansas, the Ouachita, and the Red flow eastward through fertile alluvial valleys directly into the Mississippi. On the eastern side of the valley, the principal southern rivers are the Cumberland and the Tennessee, but instead of flowing westward from the Appalachian ridge into the Mississippi, these streams describe great semicircular arcs, first swinging southward and then northward across Tennessee and Kentucky into the Ohio River and thence into the Mississippi. Their courses run through rich limestone valleys that give great and distinctive beauty to the Nashville Basin in Tennessee and the bluegrass region of Kentucky.

Population.—This geographical variety has produced a diversity rather than a uniformity of Southern folk—a diversity ranging from the isolated mountaineers of Appalachian valleys to the semi-amphibious bayou dwellers of southern Louisiana, and including the "red necks" of the southern hill country, the poor whites of the piney woods, the cattle-herding plainsmen of Texas, the peasantlike Negroes who form more than 80% of the population of some counties along the Mississippi, and the cotton-planting farmers, both great and small, who, more than any others, have constituted a "Southern" type.

In terms of the origins of its population, the South presents a pattern unlike that of the rest of the country, but which, again, shows lack of uniformity within the region itself. The contrast with the non-South lies in the fact that the South received only a small proportion of the immigrants who came to the United States after 1800, and hence it has a relatively small number of people of southern, central, and eastern European antecedents. Most of the population is descended from the settlers who arrived during the colonial period. In the 17th century, English settlers established themselves in the coastal areas of Virginia, Maryland, and the Carolinas. In the 18th century, a heavy influx of Scots-Irish (Presbyterians of lowland Scotland who had migrated first to northern Ireland and then to America) and German settlers moved southward from Pennsylvania into the southern piedmont. During the same century, the French settled in Louisiana, where their language, religion, and culture are still in evidence, and at Mobile, in southern Alabama. The Spanish at the same time occupied Florida and Texas but did not settle in sufficient force to leave an important Hispanic tradition. The most extensive influx of the 18th century was the involuntary immigration of Negroes brought as chattel slaves directly or indirectly from the west coast of Africa. The importation of Negroes had begun as early as 1619, but did not attain large numbers until after 1700. By the year 1790, however, Negroes formed more than one-third of the population in the states of Maryland, Virginia, South Carolina, and Georgia, and in 1960 they continued to form more than 20% of the population in Virginia, North Carolina, South Carolina, Georgia, Alabama, Mississippi, Louisiana, and Arkansas. Florida, Maryland, Tennessee, Delaware, and Texas had Negro populations of between 10 and 20%. Illinois, with 10.3%, was the only state outside the South where Negroes made up as much as 10% of the population.

Climate and Soil.—In terms of climate and soil, the South shows features of uniformity, somewhat more than it does in geography and in the ethnic origins of its population. Almost the entire region lies in the same latitudes as North Africa, and the climate is, in general, mild to hot. In the summers, temperatures rise, day after day, above 90° F (32° C) in the shade. But the maximum heat is less significant than the long growing season—a period of 200 to 290 frost-free days during which slow-growing crops such as cotton, rice, and sugarcane may be brought to maturity. There is also abundant rainfall, averaging 40 to 50 in. (1,000 to 1,300 mm.) per annum in the upper South and 50 to 60 in. in the Gulf Coast region.

Because of the warmth of the region, it was not glaciated during the Ice Age, and this lack of glaciation gives a distinctive quality to the soil. Except in the limestone basins of Kentucky and Tennessee, the black belt across parts of central Georgia, Alabama, and Mississippi, and the river valleys with their rich alluvial deposit, the soil is predominantly of coarse texture and of mediocre fertility, with high proportions of clay in the piedmont region,

with its "red hills," and of sand in the coastal districts. Soil exhaustion has occurred widely in these areas, both because of their natural lack of fertility and because of the soil-depleting effects of the cotton and tobacco cultures. As a result, the South regularly consumes about half of the nation's output of commercial fertilizer. Also, erosion has occurred very widely in the piedmont area because of the torrential rains, coupled with the exposure of the soil in plowed hills and furrows which are used in the row cropping of cotton and tobacco. This erosion had been so severe that by 1930 the South had suffered a total loss of fertility in 22,500,000 ac. of its land—an area larger than the entire state of South Carolina.

Crops.—The one feature above all others that has made the South historically a distinctive and somewhat homogeneous region is the fact that, for more than three centuries, it relied almost wholly upon an agricultural economy, centred upon staple crops that were cultivated for sale on the world market. Even as late as 1948, the South still derived twice as much of its income from agriculture (16%) as did the non-South (8%). The first of these crops was tobacco, first cultivated in Virginia about 1612, just five years after the founding of the colony. Tobacco culture spread into Maryland and northern North Carolina, and for nearly 200 years it provided the chief export product of North America. Meanwhile, rice about 1698 and indigo about 1744 took hold in the Carolinas and quickly grew to dominate the economy of the coastal part of that colony. The culture of sugarcane was successfully launched in French Louisiana in 1794, and it also expanded to become the chief economic activity of the region. But none of these crops rivaled cotton, which created Southern wealth, shaped Southern institutions, and, as "king cotton," grew to symbolize the whole South at the height of its power.

The long-fibred, or black-seed, cotton was profitably cultivated on the coastal islands of Georgia and Carolina before the American Revolution, but the only strain that would grow in most areas on the mainland was the short-fibred, green-seed plant. The latter seemed commercially worthless because the lint clung so firmly to the seed that the separation of the fibres was impracticable. This situation was suddenly changed in 1793, however, when Eli Whitney, a Connecticut Yankee teaching school in Georgia, invented a device, known as a cotton gin, to separate the fibres. Whitney's gin made it possible for the South to supply cotton for a world textile market in which the new technology of mechanical spinning and weaving had created an insatiable demand for raw material. The production of Southern cotton doubled every decade between 1800 and 1861, until it reached 4,400,000 bales in 1861. As this growth took place, the staple-crop economy spread into the Gulf Coast region and within a single generation the South expanded from the Oconee River in Georgia to the banks of the Brazos in Texas.

The Plantation System.—The staple-crop economy of tobacco, rice, indigo (declining sharply after the Revolution), sugarcane, and cotton shaped the character of the South. Since production on a big scale was profitable, large agricultural units known as plantations grew up; although vast numbers of small, owner-cultivated farms remained, the plantation became a dominant factor. Since the crops were used for commercial purposes rather than for subsistence (such as prevailed in the backwoods), it paid the proprietor to employ labour and thus increase production. The slow-maturing crops needed attention most of the year and thus required a permanent labour force. Because the agricultural tasks were simple enough to be performed by unskilled labour working in gangs, owners resorted to the use of Negro slaves. Thus the one-crop system, the plantation unit, and the presence of a biracial population, with the Negroes in a subordinate position, were all developed in the South early in the 18th century, and their grip was tightened by the overpowering rise of the cotton economy. By 1850 there were 3,204,000 slaves in the South and it was estimated that 1,815,000 of these were connected with the cultivation of cotton.

Ultimately, the complex of staple crops, plantations, and Negro cultivators (whether slave or free) gave to the South qualities that made it a distinctive region and set it in an adverse sectional relationship to other parts of the United States. But until the 19th century, the sectional alignment was far from clear-cut. Historians now reject a once-prevalent interpretation which explained the differences between North and South in terms of the dissimilarities between Puritans in colonial New England and cavaliers in colonial Virginia. The British colonists who settled the two regions were not so sharply differentiated as the tradition has claimed. Moreover, in the colonial South, the plantation economy and slavery were rather narrowly confined to limited areas around Chesapeake Bay and in the coastal district of the Carolinas and Georgia. The democratic, Presbyterian, Scots-Irish who populated the vast back country of the piedmont did not share in this regime. They practised a subsistence economy, cultivated grain crops, had no use for slaves, and were frequently at odds with the aristocratic, Anglican planters. These subsistence farmers of the interior seemed to have more in common with the similarly circumstanced settlers in the interior of Massachusetts and the backwoods of Pennsylvania than either group had with the grandees of the coastal districts—whether merchant princes in Boston, Mass., or planter-aristocrats in Charleston, S.C., and along the James River. Correspondingly, the latter groups showed a greater affinity with one another than with their neighbours to the west. The antagonism between the coastal and the interior districts was chronic, and repeatedly manifested itself in incidents of friction such as Shays's Rebellion in Massachusetts and the uprising of the Regulators in the Carolinas. At the time of the American Revolution this east-west division seemed likely to remain the primary line of sectional cleavage.

North-South Differences.—At that time, the divisions between North and South still remained somewhat tenuous. The leaders of both sections agreed in regarding slavery as an evil. At the same time, both sections practised it, and it was sanctioned by law in every state. The actual concentration of slaves was overwhelmingly in the South—94% of all slaves in 1790 were held south of Pennsylvania. But many districts in the South had almost no slaves, and slavery was widely regarded as a localized and declining institution.

Between 1775 and 1830, however, both North and South experienced transformations that heightened their dissimilarities and generated deep antagonisms between them. The Northern transformation came as the region slowly began to industrialize. This process committed it politically to the idea of economic self-sufficiency within a national market protected by tariff walls, where agricultural areas and manufacturing areas would complement one another by producing to meet each other's needs and serving as markets for each other's products. Industrialization generated rapid economic change in the North, and this gave sanction to the idea of progress and to the idea of a free society in which the individual can alter his occupation and status to meet changing conditions. Moreover, the use of machines freed the worker from many brute tasks and, by increasing productivity, raised the standard of living. Both of these developments tended to enhance the dignity of the worker.

Meanwhile, in the South the advent of the cotton economy made it possible to convert the whole region to staple-crop agriculture, as had never been possible with tobacco, rice, and sugar. Cotton would grow almost everywhere in the South and it was more flexible than other staple crops in lending itself to production on any scale, large or small. The cotton economy moved quickly into the up-country, thus obliterating the former divisions between the coastal and the piedmont areas. By carrying the plantation and slavery with it, it increased the value of slaves and reinvigorated the declining slave system.

Economically, the South looked to the British textile industry for its market, and it therefore opposed the growing economic nationalism of the North and West. Socially, the plantation system discounted the commercial values of thrift, prudence, enterprise, and progress; it exalted qualities of magnanimity, command, manly prowess, and physical courage; and it adopted a cult of chivalry, with a code duello, to enshrine these virtues. The Southern social philosophy, holding to a country-gentry ideal, presented a sharp contrast with that of the North, for it stressed the con-

servative values of status in a fixed social order rather than of freedom, of stability rather than of progress, and of a way of life rather than accumulation of wealth. Such an emphasis was almost inevitable in a region where one-third of the population occupied a position of fixed legal subordination.

The Slavery Controversy.—The growing divergence between North and South, as well as the dissimilarities in their values, found a focus in the question of slavery. In the North, the antislavery sentiment of the Revolutionary era continued to grow. Between 1777 and 1804, every state north of Maryland either abolished slavery outright or provided for gradual abolition. The early antislavery movement was moderate in tone and sought to bring about emancipation gradually by persuading slaveowners to free their slaves voluntarily. But about 1830 it entered a new and more militant phase in which immediate abolition was demanded and slaveowners were denounced in most abusive terms. The militant abolitionists were always a minority, and historians disagree as to the extent to which the North became "abolitionized," but it is clear that antislavery sentiment became very widespread. The immense popularity of Harriet Beecher Stowe's *Uncle Tom's Cabin* (1852) and the election to the presidency of Abraham Lincoln, who had said that "if slavery is not wrong, then nothing is wrong," serve as indexes to this feeling.

While the North passed from mild opposition to strong condemnation of slavery, the South passed from mild opposition to an unqualified defense of the "peculiar institution." Various Southern spokesmen defended slavery on the ground that it was sanctioned by the Bible, that the economic exploitation of wage earners was worse than the exploitation of slaves, that the Negro was biologically inferior, and that in a well-ordered society it was better for one class to be set apart for the menial duties. Belief that slavery was a positive good became a test of Southern orthodoxy.

With all the cultural dissimilarities and economic conflicts of interest between North and South converted into a dispute on the slavery question, sectional antagonisms were chronically acute between 1830 and 1860. The South perceived that it was not growing as rapidly as the industrial North in wealth, power, or population. A minority psychology became fixed upon the whole region, and a number of its political leaders, of whom John C. Calhoun was foremost, developed elaborate constitutional arguments, proclaiming the ultimate sovereignty of the states and their right to secede from the union. The full explosive effect of the slavery question was to some extent kept out of politics by the fact that no one contested the right of individual states to permit or prohibit slavery within their own borders. But whenever new lands were acquired, either by the Louisiana Purchase (1803) or by the War with Mexico (1846–48), bitter contests took place over the status of slavery in these areas prior to statehood. Thus there was a series of crises: in 1820 over slavery in the Louisiana territory; in 1832–33 over South Carolina's effort to nullify the tariff act; and in 1848–50 over slavery in the territory acquired from Mexico. In each of these crises a clash was averted by the adoption of measures of compromise, which have been compared to treaties between two nations. But despite these efforts to save the Union, relations between the sections became increasingly strained and were brought almost to the breaking point by a series of violent episodes in the 1850s—the repeal of the Missouri Compromise by the Kansas-Nebraska Act in 1854, open combat between antislavery and proslavery factions in "bleeding Kansas," the decision of the Supreme Court in 1857 in the Dred Scott case that Congress could not prohibit slavery in the territories, and John Brown's raid at Harpers Ferry, in 1859. Finally, in 1860, Abraham Lincoln was elected president on a platform pledging opposition to slavery in the territories, and by a purely sectional majority. The states of the lower South took his election as a signal to act. Seven of them (South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, Texas) adopted ordinances of secession, and proceeded (1861) to form a new union, the Confederate States of America (*q.v.*).

Lincoln denied the legality of their act and sought to maintain the authority of the Union. As a result, fighting began at Ft. Sumter, in Charleston Harbour (April 1861). Soon thereafter, four other states (Virginia, North Carolina, Tennessee, Arkansas) also seceded and joined the Confederacy. For four years, the United States and the Confederate states fought each other fiercely in the American Civil War (*q.v.*).

Southerners in the heat of secession and war believed that the "Southland" or "Dixie," as they now called it, had achieved a full and separate nationality, not only in the political but also in the cultural sense. Historians since then, with an eye to features of cultural distinctiveness, have also recognized an important degree of "Southern nationalism." It is a serious question, however, whether Southern separatism resulted primarily from deep cultural differentiation, or whether it was the reaction of a group who were still an integral part of the American people, but who had been psychologically (rather than culturally) alienated from their fellow Americans by a long period of minority status, conflicting interests, and defensive guardianship of the institution of slavery. The readiness with which the South returned to the Union after the war suggests the latter.

The Reconstruction Era.—At any event, the South lost the war, and this loss settled two questions. First, it killed the idea of state sovereignty and secession. Second, it ended the institution of slavery. But there were other problems which the war did not solve, and which continued to make for Southern distinctiveness for another century. For one thing, the South continued to rely on a one-crop economy, and it continued to cultivate this crop with the labour of Negroes, who discovered that as long as a man went on making his living by hoeing cotton, the transition from slavery to freedom did not altogether revolutionize his life. For another, the South continued to insist upon the inferiority and the subordination of the Negro. Slavery had been partly an economic system for the ownership of labour and partly a social system of racial control, and though emancipation ended the one, it did not end the other.

During the so-called Reconstruction period (1865–77), the victorious Republican Party made more or less earnest efforts to assure Negro equality, but those who wanted the party to help the Negroes were probably never as numerous as those who wanted the Negroes to help the party. After the latter perceived that the party might fare better without Negro help, the crusade for equality was generally abandoned, and the South was left to work out its own arrangements. As a consequence, the institution of slavery was replaced by three institutions: the economic system of sharecropping, the political system of one-party politics, and the social system of segregation, supported both by law and by custom.

Sharecropping.—The system of sharecropping or tenancy resulted from need for a new link between the soil and the cultivator. The former slaves lacked funds to buy land; the landowners lacked funds to pay wages. Hence, an agreement was made that the landlord would furnish the land, the freedman the labour, and each would receive a share of the proceeds for his contribution. The cultivator, however, necessarily received the necessities of life on credit during the annual periods between harvests, and the cotton economy was so unprofitable that the tenant's share seldom left a decent surplus after his debts had been settled. Thus Southern tenant farmers were chronically in debt; their indebtedness limited freedom to move or change occupation; and they had a lower standard of living than any other large group in the American population. Moreover, the chronic overproduction of cotton, with its attendant low prices, forced more and more small landowning farmers into tenancy. Between 1880 and 1930 the proportion of Southern farms operated by the tenants increased from 36 to 55%. During the last 30 years of this span, white tenants increased by 400,000 and Negro tenants by 147,000, so that what had begun as an arrangement for the freedmen became more and more a biracial institution.

One-Party System.—The one-party system was an arrangement to neutralize the political power of the Negroes, who had legally been enfranchised by the 15th Amendment (1870). After a brief period of Southern support for Populism in the 1890s, Southerners conducted their political activity solely within the Democratic Party. Contending that the Democratic Party was a private and not a public instrumentality, they excluded Negroes

from participation in the primary elections in which party nominees for office were chosen. Moreover, between 1890 and 1910, most Southern states placed in their constitutions literacy and property qualifications from which large groups of whites, at least in some states, were exempted by clauses allowing them to qualify if their forebears had voted before 1860 ("grandfather clauses"). By these devices, by inequitable enforcement procedures, and by a relatively costly poll tax which most Negroes found difficult to pay, Negroes were effectively excluded from political life. At the same time, the white "solid South" remained Democratic: 11 states from Virginia to Texas elected only four Republican governors between 1876 and 1960. Because of this concentration in one party, Southerners gained a disproportionate share of committee chairmanships and tended to dominate the U.S. Congress during Democratic administrations. After the 1964 presidential election, when the Republican nominee carried five Southern states, some political observers predicted the eventual demise of one-party rule in the South.

Segregation.—The third of the institutions succeeding to slavery was legalized segregation. The practice of segregation, it may be noted, was far older than the segregation laws and it extended far beyond the South. Throughout the United States, Negroes were generally denied access to places of public resort. They were excluded from trade unions, forced to live in segregated residential areas, prohibited from marrying whites, and prevented from mingling freely with the rest of the population. In most areas, this was done informally or by extralegal devices such as restrictive housing covenants, but in the South it was done by law. Among Southern segregation laws, the statutes requiring segregated education were important. Laws requiring Negroes to use segregated railroad facilities were upheld as constitutional by the Supreme Court in the case of *Plessy* v. *Ferguson* (1896).

Economic Trends.—Until 1932 the South remained an impoverished and undiversified region. The growth of a textile industry in the Carolinas, and the movement to develop a "new South" after the Civil War had not seriously qualified the region's commitment to cotton, to agriculture, and to a rural way of life. The Negroes remained a kind of peasantry and the income of the South stood at only $372 per capita in 1929, while income outside the South was $797 per capita. But after 1933 the South experienced an economic revolution, resulting partly from the New Deal and the collapse of cotton tenancy and partly from rapid economic diversification and industrialization.

During the depression that began in 1929, cotton prices sank to a point that bankrupted the cotton economy. The plight of the sharecropper was desperate and cultivation continued only because of the lack of alternatives. When this situation was at its nadir, the government stepped in with two devices that exercised an effect more revolutionary than was intended. Agricultural benefit payments for taking acreage out of production led landlords to curtail sharecropping operations. Partly because of this and partly because of the nationwide shift of population to the cities, the number of tenant farms in the South declined from 1,791,000 in 1930 to 366,000 in 1959, while the number of Southern nonwhite tenants declined from 600,900 to 123,000. The second New Deal device was the system of unemployment relief, which drew Negroes temporarily to Southern towns where relief payments were issued. During and after World War II, however, there was heavy Negro migration to Northern industrial centres. By 1960 the proportion of Negroes who lived in the South was only 60%, whereas in 1920 it had been 85%. By 1960 the average Negro was no longer a rural-dwelling, sharecropping, cotton cultivator but was a city-dwelling, wage-earning industrial worker.

With World War II and its aftermath, industrial developments and diversification revolutionized the economy within the South. Military installations were heavily concentrated in the South during the war, and after the war several new industries enjoyed spectacular growth. In 1948 the value of cotton produced was $2,189,000,000, but this amount was surpassed both by the value of livestock ($3,072,000,000) and of textiles ($2,832,000,000), and was rivaled by the value of chemical products ($1,082,000,000), lumber products ($889,000,000), petroleum products ($642,000,000), and paper products ($539,000,000), all of which had increased by more than 247% in the preceding eight years. Cotton was no longer king.

As a result of this economic change, the percentage of workers in the South employed in agriculture declined sharply. Also, the proportion of Southerners living in cities rose from 15% in 1900 to more than 55% in 1960 (compared with a national increase from 39 to 70%). But perhaps the most drastic change of all was reflected in the greater increase of per capita income in the South. While such income was rising from about $700 to $2,600 for the U.S. as a whole between 1929 and 1964, it rose from about $350 to more than $1,900 for the Southern states.

Desegregation.—At the middle of the 20th century, the steady growth of industrialism, urbanization, and wealth were constantly diminishing those factors of poverty, agrarianism, and ruralism that had operated to preserve the South's historical traditions and its distinctive identity. But although the distinctive elements in the Southern region had been much reduced, the Southern adherence to a biracial system remained strong enough to assert itself with powerful force when challenged in 1954.

From about 1905 (when a protest was framed by Negro leaders at Niagara, N.Y.), there had been a rising demand in liberal circles for the elimination of discriminatory practices toward Negroes, and after about 1927 (when the white primary was ruled invalid), the Supreme Court began to interpret the guarantees of the 14th Amendment as prohibiting various forms of discrimination. For many years it did not question the legality of segregation in cases where facilities were "separate and equal," but in 1954 in the case of *Brown* v. *Board of Education*, it reversed the *Plessy* v. *Ferguson* decision and declared that segregation in publicly supported schools was unconstitutional.

Sectional antagonisms flared again as the Southern states denounced "judicial usurpation," and invoked the principle of local self-government, while liberals criticized the South for racial prejudice and for the defiance of federal authority. Eleven states (Virginia, North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, Texas, Arkansas, and Tennessee) adopted laws to avoid, directly or indirectly, the integration of the schools, and "citizens' councils" were organized to resist it. In the border states, where resistance was not so strong, desegregation achieved several relatively quick and easy triumphs, as in Washington, Baltimore, St. Louis, and notably Louisville. But in the lower South, resistance was determined, federal court orders were resisted, and some states adopted policies of "massive resistance." By 1965, partly because of continued Southern segregation and partly because of generalized race discrimination throughout the country, Negro unrest had become intense and mass demonstrations were taking place on a wide scale. A century after the South had made its supreme assertion of a separate identity, and after many decades of steady decline in the significance of the differentials that distinguish the South, the historical heritage of the South's biracial system was still strong enough to create a major sectional issue and to induce a high degree of Southern solidarity in asserting local autonomy as opposed to uniform national policy. In the presence of this immediate issue, the less tangible aspects of Southernism—its emphasis upon the virtues of the agrarian way of life, its conservative concept of the social order, its ideal of social standards set by the leaders rather than by the masses—were so much overshadowed that it is difficult to estimate the extent to which these features, by themselves, would have continued to make the South a significant and distinctive entity.

SOUTH AFRICA, REPUBLIC OF (Republiek van Suid-Afrika), a country occupying the southernmost part of the African continent between the Atlantic and Indian oceans. From 1910 to 1961 it was known as the Union of South Africa, a constituent part of the Commonwealth of Nations, comprising the former British colonies of Cape of Good Hope, Natal, Transvaal, and Orange River Colony, which became the four provinces of the Union, the last named being known since union as Orange Free State.

The southern, western, and eastern limits of the republic are formed by the coastline. Landward it is bounded on the northwest by South West Africa, on the north by Bechuanaland (which achieved independence in 1966 under the name Botswana) and Rhodesia, and on the northeast by Mozambique (Portuguese East Africa) and Swaziland. The area of the republic is 471,445 sq.mi. (1,221,044 sq.km.). The administrative capital is Pretoria; Cape Town is the seat of the legislature.

South West Africa (*q.v.;* 317,827 sq.mi.), formerly a German possession, was mandated to the Union after World War I and is administered as part of the republic. Within the confines of the republic, but not part of it, lies Basutoland which became independent in 1966 and took the name Lesotho.

In December 1947 South Africa formally annexed two small subantarctic islands, Prince Edward and Marion, which lie in the Indian Ocean approximately 1,200 mi. (1,900 km.) SE of Cape Town.

This article is divided into the following sections and subsections:

I. PHYSICAL GEOGRAPHY

1. Geology and Structure.—Geological formations of South Africa range from some of the oldest rocks of the earth's crust to the most recent formations. The oldest rocks include metamorphosed sediments and lavas of the Swaziland or Kheis system which, together with other more restricted formations, form the Archean complex. Gold and other minerals are associated with these rocks. Next in age are the Proterozoic formations, the oldest of which is the Dominion Reef system of lavas and sediments. This is followed by the Witwatersrand system, 25,000 ft. (7,600 m.) thick, consisting mainly of quartzites and shales with thin reefs of "banket" (quartzitic conglomerates) from which most of the gold of Transvaal and Orange Free State is derived. Next come the Ventersdorp system of lavas and sediments, and the Transvaal system consisting of Black Reef quartzite at the base followed by dolomite and a succession of quartzites, shales, and lavas of the Pretoria series, the system attaining a thickness of about 16,000 ft. (4,900 m.). Toward the close of the deposition of the Pretoria beds vast intrusions of basic and acid magma in central Transvaal formed a lopolith (*i.e.*, a saucer-shaped mass) of norite and allied basic plutonic rocks and the red granite of the Bushveld Igneous Complex. Now exposed by the removal of the overlying beds, this lopolith is revealed as the largest feature of its kind in the world. In these rocks are many minerals, including vast quantities of chrome, platinum, and iron. After the intrusion of the Bushveld magmatic rocks the deposition of the sandstones and conglomerates of the Loskop, Matsap, and Waterberg systems took place in the late Precambrian.

In the Paleozoic, deposition continued with the formation of the Nama system, of quartzite, limestone, and shale, now found in western Cape Province and in southern South West Africa. The Cape system followed; at its base the Table Mountain Sandstone series, 5,000 ft. (1,500 m.) thick, forms most of the prominent mountain features of the western Cape, including Table Mountain itself. The Bokkeveld series of sandstones and shales, 2,500 ft. thick, was next deposited and the third series, the Witteberge, of whitish sandstone, terminated the deposition of the Cape system. In Permian times the whole system was strongly folded. In the Carboniferous the deposition of the Karroo system, which now covers a greater area of the republic than any other formation, began. Having a maximum thickness of about 25,000 ft., the system is divided into the Dwyka, Ecca, Beaufort, and Stormberg series. At the base of the Dwyka series is the Dwyka tillite, which was followed by sandstones and shales with numerous doleritic intrusions and crowned in Basutoland with lava sheets now about 4,000 ft. thick—the Stormberg (or Drakensberg) lavas, probably of early Jurassic age. Except in the Cape folded zone and the eastern area affected by the Natal monocline, the Karroo sediments have remained almost horizontal.

During the Cretaceous there was intense erosion and deposition in the valleys of the Cape folded zone and marine deposition along the south and east coasts; these movements brought into being the valley conglomerates and the estuarine sandstones and clays of the Uitenhage series, and the coastal limestones of Zululand. Deposition continued into the Tertiary in the coastal areas, forming the limestones of the Alexandria and Bredasdorp formations in the south and southwest, and in the east the Zululand Tertiary limestones.

In the plateau basin of the interior (the Kalahari Basin) to the north of the Orange River, the Kalahari system has been deposited, at first apparently under fluviatile conditions and later by eolian action. The basal gravels and partly cemented sands are covered by a mantle of loose, unconsolidated Kalahari sand, generally reddish in colour but grayish in damp localities, the whole formation having a maximum thickness of about 1,000 ft. The sand mantle extends continuously northward into the southern part of the Democratic Republic of the Congo.

2. Physiography.—The surface of South Africa may be considered as having two generally distinct physiographic elements: the plateau surface and the surface between the plateau edge and the coast, which may be called the marginal areas (*see* also *Geographical Regions* below). Separating these two divisions is the plateau edge, or the Great Escarpment, which is the feature formed by the headward erosion of the drainage of the marginal area. This escarpment is sharply defined or indistinct depending on whether the plateau rocks are hard-overlying-soft or generally of undifferentiated hardness. Thus the boldest part of the escarpment lies along the border of Lesotho and Natal where the Stormberg lavas overlie the softer Stormberg sandstones. There is formed the Natal Drakensberg, with spectacular peaks such as the Mont-aux Sources (10,822 ft. [3,299 m.]) in the north and Champagne Castle (11,072 ft. [3,375 m.]) and Giant's Castle (10,868 ft. [3,313 m.]) farther south; the highest point so far surveyed near the plateau edge, and the highest point in South Africa, is Thadentsonyane (Thabana-Ntlenyana) (11,425 ft. [3,482 m.]), about 15 mi. (24 km.) SW of Giant's Castle. The height of the scarp above the comparatively flat surface of the Natal high veld is about 6,000 to 7,000 ft. (1,800 to 2,100 m.). To the north of the Natal Drakensberg the Stormberg lava does not cap the Karroo sediments and the plateau edge is less well defined; but in eastern Transvaal another structural element, the Black Reef quartzite of the Transvaal system, is responsible for the boldness of the escarpment, which is there known as the Transvaal Drakensberg, its highest point, Mt. Anderson, a little behind the Black Reef escarpment itself, being 7,498 ft. (2,285 m.). To the north of the Black Reef quartzite the escarpment is cut in granite and is generally not well defined.

The southern edge of the plateau is given prominence by the presence of strong dolerite sheets which sharply define the Sneeuwberg (Snow Mountains) to the north of Graaff-Reinet, where the dolerite Compass Berg has an altitude of 8,215 ft. The Nieuwveld escarpment to the north and west of Beaufort West is of similar formation. The western edge of the plateau is cut in the south in Karroo beds (the Roggeveld—*i.e.*, Rye Veld—Mountains), in the middle in the Table Mountain Sandstone (the Bokkeveld—*i.e.*, Goat Veld—Mountains), and in the north in granite, the Nama beds and the rocks of the Richtersveld complex. It is continued in South West Africa.

Within the Great Escarpment the plateau surface ranges in altitude from about 3,000 ft. in the west to nearly 11,500 ft. in the east. Two types of plateau surface are distinguishable: the Karroo surface and the pre-Karroo surface, now being exposed by erosion. On account of the predominantly horizontal lie of the sediments and their association with dikes and sills of hard dolerite, the Karroo surface is tabular in character. Great expanses of flat surface are broken by table mountains and koppies (hillocks), generally formed by dolerite capping soft shales or sandstones. In the eastern part of the plateau the Stormberg lavas and the vigorous erosion of the Orange River headwaters have given the Basuto Highlands a rugged, dissected character. The pre-Karroo surface has a more diversified topography chiefly because of the greater variety of the rocks. Where the rocks are hard and disturbed the surface is generally rugged, with prominent ridges of quartzite or ironstone and deep valleys formed by the softer rocks. The quartzite ridges of the Witwatersrand are of this character, as are also the Magaliesberg group of ridges which form much of the margin of the Transvaal bushveld basin. In northern Transvaal the Zoutpansberg ridges are of a similar type, the quartzites dipping toward the Limpopo Trough. Where, however, the pre-Karroo rocks are more nearly horizontal, local plateau surfaces are formed such as the Waterberg Plateau in western Transvaal and the Kaap Plateau in northwestern Cape Province. At the northern boundary of Transvaal the low floor of the middle Limpopo Basin is the result of large-scale trough faulting.

In the marginal zone below the plateau edge prominent features are largely caused by the vigorous erosion of steeply graded streams. Thus hard rocks, such as the quartzites and ironstones of the Swaziland system, form the prominent ridges of northern Swaziland and adjacent Transvaal. The Lebombo Mountains, along the eastern border of Transvaal, are low ridges, about 1,500 to 2,500 ft. above sea level, formed of Karroo lavas dipping steeply eastward. In the midlands of Natal, monoclinal folding has given the Karroo beds a steep eastward dip.

The main ridges in this region

PROVINCES, MAJOR CITIES, AND TOWNS IN THE REPUBLIC OF SOUTH AFRICA

are gigantic spurs jutting out from the Drakensberg between the marginal stream valleys. In the south the marginal zone contains the "Cape folds" of Permian age. In the western part of the folded zone the anticlinal ridges of Table Mountain Sandstone run nearly north-south, slightly arcuate and concave to the coast. Two main lines of ranges are distinguishable: to the west the Hottentots Holland Mountains, stretching northward to the Olifants River Mountains, and to the east the Cedarberg line trending from just south of Vanrhynsdorp toward Ceres. The highest point in this western zone is the Great Winterhoek Mountain, 6,815 ft. In the eastern part of the folded zone two main ranges trend eastward, slightly concave to the south: the northern range, known by various names, may be called the Swartberg; the southern range is the Langeberg line. Between these two is a third rather fragmented series of ridges which may be called the Kammanassie line. The highest peak in this eastern zone is the Seven Weeks Poort Mountain, 7,632 ft. Between the folded zone and the coast is the coastal foreland and between the Langeberg line and the Swartberg lies the Little Karroo Basin. Between the folded belt and the Great Escarpment is the erosional basin known as the Great Karroo (*see* also KARROO).

Hydrography.—The main physiographic division between the interior plateau surface and the marginal area is reflected in the drainage systems of South Africa. The plateau river systems are much larger than the marginal systems; the two most important rivers draining the plateau are the Orange (with its affluent the Vaal), which flows into the Atlantic Ocean, and the Limpopo, which discharges into the Indian Ocean through Portuguese East Africa. (*See* further ORANGE RIVER; VAAL; LIMPOPO.)

There are very few lakes in South Africa, and although there are natural hollows on the surface of the land, most of these are filled with water for only part of the year. These accumulations of water are called pans (Afrikaans *panne*) and are found especially on the flatter outcrops of the Dwyka and Ecca beds of the Karroo system where the surface has been weathered into shallow hollows. The sandveld of Orange Free State has many pans (of sizes ranging up to about 12 sq.mi. [31 sq.km.]) because percolation is hindered by the presence of hardpan two or three feet below the surface. The water in pans may be saline, brackish, or almost fresh.

In contrast to these flat areas, where occasional heavy rain results in sheets of standing water, are sloping surfaces which are vulnerable to erosion by swift-moving water. If the protective vegetation cover is removed by burning or close grazing, soil is exposed to the attack of heavy rain and inches of topsoil may be washed downhill in a single storm. Runoff may concentrate in tracks made by animals going regularly to water holes, and as these bare paths offer no check to running water they are quickly attacked and dongas (gullies) are formed. Cultivated land in parts of the eastern region of heavy summer rainfall has been gashed by dongas and lesser runnels called rills.

Coasts.—The comparative straightness of the northern part of the west coast is probably due to the granite character of this area and the lack of large rivers. The southern part has the large inlet of Saldanha Bay. Lack of fresh water in the vicinity led to its abandonment as a harbour in favour of the more exposed Table Bay, where abundant fresh water was available. Table Bay is backed by the spectacular Table Mountain (*q.v.*) and by the Cape Peninsula which ends southward in Cape Point, the "Cape of Good Hope." On the south coast the chief features are False Bay, Cape Agulhas (Portuguese "needles"; the southernmost point of Africa), and several other capes. At the eastern end Algoa Bay is typical of bays formed by erosion of the softer rocks between Table Mountain Sandstone outcrops. The east coast is remarkable for its straightness, which is thought to be caused by crustal bending and faulting. Earthquakes off the coast of Zululand indicate present crustal instability.

Off the south coast lies the Agulhas Bank extending about 130 mi. (210 km.) SSE of Cape Agulhas, where its depth is about 130 fathoms. Certain parts of the bank are favourable for fishing. Off the west coast, about 7 mi. (11 km.) from Cape Town, lies Robben Island, formerly noted for its seals (Dutch *robben*). The island, about 2¼ mi. long and 1¼ mi. wide, has been the site of a prison settlement, a leper asylum, a defense base, and again a prison station. The seals have entirely disappeared.

3. Climate.—South Africa is dominated by the tropical belt of high atmospheric pressure which encircles the globe between the latitudes of about 25° and 30° S. In the winter months this belt is continuous over land and sea; in summer it is broken by the occurrence of low pressure systems over the land surfaces. In summer, therefore, a monsoon effect is produced by the occurrence of the "low" over South Africa and the "highs" which move eastward and northeastward along the south and east coasts. The interplay of the wind systems resulting from this general relationship affects both the temperature and the rainfall.

Actual temperatures are strongly affected by altitude, which offsets to some extent the normal increase of temperature resulting from decrease of latitude. From the south coast northward the temperatures increase little except in the lowland areas. At the coast Port Elizabeth has a mean annual temperature of 17.8° C (64° F); Graaff-Reinet, at an altitude of 2,440 ft. in the Great Karroo Basin, 17° C (63° F); Johannesburg (5,750 ft., on the high veld) 16° C (61° F); Pietersburg (4,244 ft., northern high veld) 17° C; Messina (1,800 ft. in the Limpopo Trough), 23° C (73° F). The monthly range of temperature is least at the coast and greatest in the interior. Thus the range between the mean monthly temperatures of January and July is for Port Elizabeth 6.7° C (12° F), Graaff-Reinet 11.7° C (21° F); Johannesburg 11.1° C (20° F); Pietersburg 10.6° C (19° F); Messina 9.4° C (17° F).

There is also a marked effect of the coastal currents; the cold Benguela Current flowing northward along the west coast gives low temperatures to the west coastal areas, while the warm southwestward-flowing Mozambique Current on the eastern side of the subcontinent is responsible for the higher temperatures of the eastern coastal areas. Thus on the west coast Port Nolloth has a mean annual temperature of 13.9° C (57° F); the corresponding temperature of Durban on the east coast is 21.1° C (70° F).

Frost occurs over most of the interior plateau and in the higher parts of the marginal zone. The mean duration of the frost period is highest in the Basuto Highlands (more than 180 days) and lowest in the low veld and coastal areas where frost rarely occurs except occasionally in the valley bottoms. The duration of sunshine varies from more than 80% of the possible duration in northern Cape Province to 70% over most of the remainder of the interior, and to less than 60% in the coastal areas.

Three fairly distinct rainfall regions can be recognized according to seasonal occurrence: the summer, the winter, and the all-season regions. In the centre and east of the republic the rainfall has a predominantly summer incidence, being mainly monsoon in character and often associated with heat thunderstorms. The moisture is brought into the interior by winds with an easterly component blowing toward the continental low pressure area developed over the southern Kalahari. There is thus a gradual progression of the summer rainfall from the east coast toward the northwestern part of Cape Province from August to January, and a recession eastward from February to May. Except along the east coastal zone little rain falls in this area in the winter. The highest rainfall in this eastern area occurs on the Great Escarpment, where the average annual precipitation is in places more than 60 in. (1,525 mm.), on other high mountain features, and on parts of the eastern coastal belt. The summer rainfall is mostly of high intensity, which, coupled with high evaporation, reduces its value for agriculture and increases its soil-eroding tendencies.

In the southwest of the republic is the winter rainfall area in which the rain occurs mainly from May to October. This rainfall is mainly cyclonic and orographic in type, occurring most heavily on the mountain ranges where annual falls of 200 in. (5,080 mm.) are not uncommon. In the coastal lowlands the highest annual averages are about 25 in. (635 mm.); to leeward of the mountain ranges the averages fall sharply to about 10 in. (255 mm.) or less. In the third region rain may fall in any season. Thus in the south coastal area rainfall is almost evenly distributed through the year and varies between 20–30 in. (510–760 mm.), while in the narrow

corridor in the interior, between the margins of the summer and winter rainfall areas, average annual rainfall is generally less than 10 in.

For the republic as a whole, it is estimated that about 30% of the surface receives on an average less than 10 in. of rain a year; about 34% receives between 10 and 20 in., 25% between 20 and 30 in., and the remainder more than 30 in. The reliability of the annual rainfall varies from 70% in northwestern Cape Province to about 85% in the southern and eastern coastal areas and to more than 90% along the western part of the south coast. It is estimated that about 51% of South Africa is in drought once every five years, 38% once in three years, and 24% once in two years, drought being defined here as the occurrence of less than 85% of the average rainfall for the year.

4. Vegetation.—The vegetation of South Africa may be divided into five main types: forest, savanna, grasslands, semidesert and desert, and sclerophyll or Cape maquis.

Forest.—Two general types of forest can be recognized, the temperate and montane and the eastern subtropical and tropical. The largest area of temperate forest is situated in the eastern part of the south coastal zone where mean monthly temperatures range from about 12° C (53° F) to about 22° C (71° F) and the mean monthly rainfall from about 1½ to 4½ in. (40–115 mm.). The best-known part of this association is the Knysna Forest in which the main trees include the tall yellowwoods (*Podocarpus* species), growing to a height of 150 ft. (45 m.), the black ironwood (*Olea laurifolia*), the Cape beech (*Myrsine melanophloeos*), the stinkwood (*Ocotea bullata*), and the sneezewood (*Ptaeroxylon obliquum*). Similar associations occur in smaller areas on the south-facing slopes of the Cape mountains, especially on the Hogsback and Amatola escarpments, and in the Natal midlands where, however, only small remnants of the former great forests are left. In eastern Transvaal large forests formerly covered the escarpment of the Transvaal Drakensberg, but these have been exploited for mining operations and the largest natural forest in this area is now conserved in the Woodbush Mountains. The subtropical and tropical forest formerly stretched along a narrow zone behind the east coast where the rainfall is 30–50 in. a year.

J. H. WELLINGTON

NATURAL VEGETATION REGIONS OF SOUTH AFRICA

The dense bush and evergreen forest includes trees of the genera *Sclerocarya, Protorhus, Albizzia, Trichilia,* and *Ficus.* Formerly there were valuable trees such as the Cape mahogany (*Trichilia emetica*), the Cape ebony (*Heywoodia lucens*), and the Cape box (*Notobuxus macowani*), but these have almost all been heavily exploited. (*See* also *The Economy: Production: Forestry* below.)

Savanna.—The bushveld, as it is generally called in South Africa, is generally the dominant association where the rainfall is between about 15 and 30 in. a year and frosts and cold are not severe enough to kill the young trees. The bush may be open, with sparse tree growth, or closed, with dense tree growth. Where no species is dominant the bush is termed mixed. In the republic mixed bush is the most common type, occupying most of the Middle Veld (between about 2,000 and 4,000 ft.) in eastern Cape Province and Natal, and in Transvaal covering the whole of the plateau area below the altitude of about 4,000 ft. In the drier areas the most common trees are acacias, with aloes, euphorbias, and baobabs forming a distinctive feature in northern Transvaal. In the moister parts of Transvaal deciduous broad-leaved trees dominate, among which are the maroola (*Sclerocarya caffra*), various sterculias, the South African mahogany (*Afzelia quanzensis*), and in the lower valleys various palms. The commonest grasses include the genera *Themeda, Digitaria,* and *Panicum.*

Grasslands.—These occupy the higher, cooler areas where the annual rainfall exceeds about 15 in. It is usual in South Africa to distinguish between "sweet" veld grasses, which occur mainly in the western, drier part of the grassland area, and which are nutritious and palatable to stock throughout the year, and "sour" veld, consisting of grass types that during the dry season lose their nutritious character and become woody and indigestible. On the plateau the climax type over most of the area is the red grass (*Themeda triandra*). Retrogression to the more xerophytic love grass (*Eragrostis*) follows overgrazing and soil erosion and, later, to bristle grass (*Aristida*) or Bermuda grass (*Cynodon*). In the higher elevations the grassland is temperate in character with the fescues *Festuca costata* and *F. caprina,* and *Bromus firmior* being common.

Semidesert.—Vegetation is comprised mainly of scattered Karroo shrubs and succulents, which occupy most of the area having an annual rainfall of between 5 and 10 in. The shrubs are mostly perennial woody bushes about 3 to 12 in. high and spaced from about one foot to several feet apart. The leaves are generally very small and the root systems large. The commonest include various species of *Pentzia,* the bitter karroo (*Chrysocoma tenuifolia*), and, in brack soil, various gannas (*Salsola* species) and the saltbushes (*Atriplex* species). Some of these bushes can survive a drought of nine or ten months and they form excellent subsistence feed for small stock. The succulents are of two types: low bushes, rarely more than eight inches high, with ericoid shrublets and many species of *Mesembryanthemum,* and a taller type consisting mainly of euphorbias, aloes, and *Portulacaria.* In the lower Orange River Valley the rocky slopes harbour many desert succulents.

Cape Maquis.—Cape maquis is confined to southwestern and southern Cape Province where the plants are protected against the hot, dry summers. The

shrubs are found from sea level to about 3,000 ft. With annual rainfalls of about 20–30 in. they grow to a height of about 15 ft.; near the lower rainfall limit of about 15 in. the shrubs are 3–5 ft. high, the leaves often very small and leathery. The families typical of the region are Proteaceae, Restiaceae, Ericaceae, Peneaceae, Grubbiaceae, Bruniaceae, Rutaceae, and Iridaceae. A remarkable difference between this region and most other regions of Mediterranean vegetation is the general absence of trees.

5. Animal Life.—Zoologically the republic is recognized as forming the southern part of the southern African subregion of the Ethiopian faunal region.

Mammals.—South African mammals are all placental mammals. The insectivores include little elephant shrews and golden moles. There are more than 20 genera of bats.

The primates are represented by the bush baby or night ape (*Galago*) and by the Cercopithecidae, which include the vervet monkey, the samango monkey, and the chacma baboon. The order Pholidota is represented by the Cape pangolin or scaly anteater.

The carnivores include Canidae (foxes and jackals), Mustelidae (polecat, weasel, ratel or honey badger, otter), Viverridae (civet, genet, mongoose, meerkat), Protelidae (aardwolf, hyena), and Felidae (wildcat, serval, lynx, leopard, lion, cheetah). The Pinnipedia are represented by the Cape sea lion, or fur seal, and the elephant seal, which occasionally visits the south coast. The Tubulidentata has one representative, the aardvark or antbear; the Proboscidea also one, the African elephant. Of the Hyracoidea there are two genera, the hyrax and the dassie, the former being one of the commonest mammals in the republic.

Among the odd-toed hooved mammals are the black and the white rhinoceroses and the mountain and Burchell's zebras. The even-toed ungulates include the bush pig, warthog, hippopotamus, giraffe, Cape buffalo, and about 20 genera of antelope (or buck, as they are generally called in South Africa), including duiker, grysbok, klipspringer, reedbuck, waterbuck, impala, springbok (or springbuck), gemsbok, sable antelope, bontebok, wildebeest, bushbuck, kudu, and eland. There are two genera of hares.

In point of numbers the largest order is probably that of the rodents. Six families are represented, the animals included in them being the mole rat, cane rat, squirrel, spring hare, and dormouse, but the largest family is that of the Muridae, which includes rats, mice, and gerbils. Five genera of murids are peculiar and endemic. In the South African seas are about 20 genera of whales and dolphins.

The present state of the fauna in the republic may be summarized by saying that most of the small mammals are still found wild. The larger animals, especially the carnivores and antelopes, survive only in protected areas. Lions and elephants are found now only in or near the game reserves. The larger buck are preserved on some farms and in the reserves. Smaller buck still roam wild, and the leopard and baboon, the jackal and hyena are still found in the less frequented areas. The blue antelope (bloubok) and the quagga of the Cape have become extinct. In the early 1960s the elephants of the Knysna Forest—the tallest of all African elephants—existed in a herd of fewer than ten beasts and also the Addo elephant herd had no adult bull.

Birds.—Most of the bird families are of the Ethiopian type but of the groups of families one is tropical in character, another Antarctic or southern in its origin, and yet another consists of migratory types. The tropical group consists of well-known types from the central African forests such as the parrots and lovebirds, the touracos, the rollers, and many others. These are found mainly in the eastern part of the republic, having come southward along the East African savanna corridor. The southern group includes most of the sea birds: the jackass penguin (*Spheniscus demersus*), the albatrosses and petrels, including the Cape pigeon (*Daption capensis*), the Cape hen (*Procellaria aequinoctialis*), and several shearwaters.

Of the large group of migratory birds from the Palearctic region are such well-known species as the European swallow, the martin, swift, cuckoo, willow warbler, garden warbler, yellow wagtail, tree pipit, golden oriole, and many others. Of the endemic Ethiopian families only the Promeropidae, the long-tailed sugarbirds, are peculiar to South Africa, the Cape sugarbird and Gurney's sugarbird being confined respectively to the Cape and the eastern areas. Among the other interesting species are the rock jumper (*Chaetops*), the ground woodpecker (*Geocolaptes*), the bald ibis (*Geronticus*) of the eastern mountains, the blue crane (*Tetrapteryx*), and the blue korhaan (*Eupodotis*), all of which are peculiar to South Africa. The largest number of families are in the orders Passeriformes (including, among others, the larks, wagtails, babblers, bulbuls, thrushes, warblers, shrikes, sunbirds, weavers, sparrows, and canaries); the Charadriiformes (including the plovers, phalaropes, skuas, gulls, and terns); and the Gruiformes (including the cranes, bustards, curlews, jaçanas, crakes, and coots). The family Struthionidae is represented by the southern ostrich, which is still wild in certain areas; the Sagittariidae by the snake-killing secretary bird, which is widely dispersed over the savanna and grassveld. An interesting recent newcomer is the Indian myna, which was introduced at first into Natal and now is found in southern Transvaal.

Reptiles and Amphibia.—Turtles, both aquatic and terrestrial, are well represented. The lizards, chameleons, leguans, and geckos include numerous species and subspecies native to the subcontinent. The representative of the Crocodilia is the Nile crocodile, whose southern limit on the west side of the subcontinent is the Cunene River and on the east the Tugela River.

Of the more than 100 species of snakes about 25% are poisonous. The nonpoisonous snakes include the useful mole snake and the curious egg-eaters (*Dasypeltis scabra*). The back-fanged snakes, which are moderately poisonous, include such well-known species as the skaapstekers or "sheep-strikers" and the boomslang or tree snake. Among the highly poisonous front-fanged snakes are the deadly mamba, three species of cobra, and the closely allied ringhals; *i.e.*, "ringed-neck," a spitting snake peculiar to South Africa. The vipers are represented by the puff adder and the horned adder. South Africa also possesses one species of python, which may attain a length of 20 ft., and also one venomous sea snake (*Hydrus platurus*).

The amphibians of South Africa are chiefly frogs and toads. There are no tailed amphibians, and there is only one genus of limbless amphibians. Frogs vary in size from the minute *Arthrolepis*, which may be less than half an inch, to the great bullfrog *Rana adspersa*, or *Pyxicephalus adspersus*, which sometimes attains a length of more than a foot. Among the toads one of the largest, the leopard toad, (*Bufo regularis*), is four to five inches long and is widespread in South Africa. The smallest is the tiny striped mountain toad, *Bufo rosei*, about an inch long. From the commercial point of view the most important amphibian is the aquatic, tongueless, clawed frog called the platanna (*Xenopus laevis*); it provides a dependable test for human pregnancy in the early stages.

Fresh-Water Fishes.—Of about 200 species of fresh-water fishes nearly half belong to the carp family, of which the best known is the barbel. Kurpers comprise about one-quarter, and of the remaining quarter the most numerous are the catfish and tiger fish. Trout have been successfully introduced.

Insects.—All the important orders of insects are represented in South Africa. The orthopterans are numerous and diverse, simulating leaves, flowers, sticks, and other forms. All are carnivorous. The brown locusts, which formerly swarmed over South Africa, are now destroyed in the immature stages. Termites or "white ants" are abundant in species and numbers. Many families of bees, wasps, and ants also are represented. True bumblebees are absent, but the carpenter bee (*Xylocopa*) is common and there is an immense variety of solitary wasps. There are many endemic beetles; especially abundant are the scarabs, or dung beetles, and the chafers. A few types of butterflies and moths are found in the southwest but many occur in the east, some of the genera being peculiar to South Africa. The Diptera include the culicine and anopheline mosquitoes, and the tsetse fly, which was formerly widespread in Zululand.

South African arachnids are abundantly represented by scorpions and solifuges, or hunting spiders, which flourish especially

in the hot, arid conditions of the Karroo and Namaqualand. Ground-living spiders are abundant. *Peripatus*, the wormlike "missing link" in the ancestry of insects, is endemic but is fast disappearing as the natural forest is destroyed.

Game Reserves.—In South Africa these serve the important purpose of conserving the game, much of which is in danger of becoming extinct. There are five national parks and a large number of provincial reserves. The Kruger National Park, the largest, extends for about 200 mi. along the Transvaal-Mozambique border following the Crocodile-Limpopo River, with an average width of about 40 mi. Nearly all the larger game animals (the notable exceptions being the gemsbok and the springbok) and the carnivora are found in the park, as are also the elephant, hippopotamus, and giraffe. The eland and the inyala frequent only the northern parts of the park. The Kalahari National Park is situated between the Nossob and Auob rivers in the extreme north of Cape Province. This is also known as the Gemsbok reserve on account of the large numbers of these animals in the park, but springbok also are very numerous and there are also hartebeest, eland, and kudu, and a fair number of carnivores including lion, leopard, cheetah, and wild dog. The Addo Elephant National Park, about 35 mi. N of Port Elizabeth, is notable for its small herd of elephants which, with the Knysna herd, are the southernmost of the African elephants. The Cape buffalo also thrives there, the only place now in Cape Province where it is found.

The Bontebok National Park (about 1,800 ac. [730 ha.]), about 17 mi. S of Bredasdorp in Cape Province, was formed to preserve the last remaining bontebok, of which a herd of about 150 has been established. The Mountain Zebra National Park, near Cradock in Cape Province, was formed to preserve the few remaining mountain zebras. In the 1960s these were increasing slowly. Of the provincial reserves the most notable are those of Natal. The Hluhluwe and Umfolozi reserves (in Zululand) have preserved the white and the black rhinoceros.

II. GEOGRAPHICAL REGIONS

In South Africa physiography offers the best single basis for regional division. As described above (see *Physiography*) the two primary divisions are the interior plateau and the marginal areas.

1. The Interior Plateau.—Five major regions may be recognized: the High Veld, the Middle Veld, the Transvaal Plateau Basin, the Limpopo Trough, and the Kalahari Basin.

The High Veld.—Lying between the altitudes of about 4,000 and 11,500 ft. (1,200–3,500 m.) above sea level, the southern part of the surface is formed by the beds of the Karroo system. Eroded by the Orange-Vaal headwaters, this structure gives rise to a tabular type of physiography consisting of flat plains and scattered relict mountains and koppies, generally capped by a sill of hard dolerite. The surface is ideal for farming of a pastoral type, being covered with grass suitable for cattle in the eastern part and with grass and karroo shrubs suitable for sheep and goats in the western part. Soils, however, are rather infertile except on dolerite outcrops. The summer rainfall in the eastern part (25–35 in.) is adequate for maize (corn), but not in the western part (15–20 in.), where kafir corn (a sorghum) is more suited to the drier conditions. In the east of the region, the Basuto Highlands, the high plateau surfaces provide summer pastures only; in the valleys are narrow alluvial terraces which form sheltered habitable areas in winter and provide limited cultivation of maize and kafir corn. The northern part of the High Veld region has a different type of surface. The Karroo beds have been removed by long-continued erosion exposing the pre-Karroo surface which was planed by the Permo-Carboniferous ice sheet. This surface, now being eroded by the headwaters of the Limpopo and Vaal rivers, has become more uneven than the Karroo surface as the Proterozoic quartzites, shales, and lavas have been thrown into relief. The great economic factor is the mineral content of the Witwatersrand beds, the "banket" or quartz-conglomerates of which contain the gold particles that have made the Rand the world's greatest gold field. The development of the Witwatersrand has been facilitated by the abundant coal supplies from the neighbouring Karroo beds.

The Cape Middle Veld.—This lies to the west of the High Veld at an altitude of about 2,500–4,000 ft. There is no natural boundary between these two regions, but the lower altitude of the Middle Veld is responsible for its higher summer temperatures and its greater distance from the east coast for its lower rainfall (5–15 in.). The region is thus arid to semiarid and where there is no irrigation is suitable only for small stock farming of an extensive type. Intensive irrigation is practised along the Orange River in this region.

The Transvaal Plateau Basin.—This basin, to the north of the High Veld, comprises the great Transvaal bushveld basin and its highland rims. The floor of the basin is formed mainly of norite and red granite. The norite soils are fairly fertile and repay cultivation, but the granite soils are sandy and infertile. Overlying the plutonic rocks in the northern part of the basin is the Stormberg lava which has decomposed into very fertile black clay soil; the rainfall, however, is low (25 in.) and rather unreliable. The Springbok Flats, as this part of the basin floor is called, is thus an area of mixed farming rather than of intensive cultivation. The highland rim of the basin is formed by the High Veld in the southeast, by the *bankeveld* (or cuesta) topography in the southwest and east, and mainly by the Waterberg Plateau in the north. The Pietersburg Plain and the Zoutpansberg Ranges form the extreme northern part of the region. The highest economic potentialities of the region are associated with the irrigation areas along the Crocodile, Olifants, and Marico rivers and with the smaller schemes in the valleys of the *bankeveld* marginal areas. Minerals such as chromite and platinum are present in large quantities in the plutonic complex of the basin floor and low-grade iron ore in almost inexhaustible quantities in the marginal quartzites.

The Limpopo Trough.—This is the middle portion of the Limpopo Basin. Formed mainly by large-scale faulting, the valley has an altitude of between about 1,500 ft. at its eastern end (Pafuri) and 3,500 ft. at its southwestern end (Lobatsi). With low rainfall (15–25 in.) and high temperatures this area is of little agricultural importance, being mainly suited to extensive ranching. Copper in the Messina area is the only important mineral.

The Kalahari Basin.—Only the extreme southern part of the Kalahari falls within the republic. The sand surface is more or less covered with grass and sparse tree growth and water is generally absent except in scattered pans and along the dry watercourses. The area is thus scarcely inhabited away from the river courses such as the Molopo in the east and the Nossob and Auob in the west. (*See* KALAHARI DESERT.)

2. The Marginal Areas.—In the area marginal to the plateau the eastern, southern, and western areas form fairly distinct types of country.

The Eastern Marginal Area.—The fall from the plateau edge to the coast is in many parts taken in three steps or surfaces, forming a high veld surface above about 4,000 ft., a midland surface between about 2,000 and 4,000 ft., and a coastal zone below about 2,000 ft. In Natal and the Transkei these are all areas of fairly high summer rainfall (25–40 in.) so that cultivation is generally possible, the crops being determined mainly by the temperature. On the eastern high veld surface the dominant occupation is pastoral farming, in the midlands mixed farming, and in the coastal zone of Natal the cultivation of sugarcane.

The Southern Marginal Area.—The surface is dominated by the Cape folded ranges. Agriculture is confined mainly to the well-watered coastal belt and to the irrigable valleys of the Little and Great Karroos. The Karroo vegetation is well suited to sheep and goat farming and the irrigated lands to the cultivation of lucerne and, in some areas, of fruit.

The Western Marginal Area.—The surface falls rather irregularly and the climate is too dry for any sustained agriculture to the north of about Vanrhynsdorp. Southward the area between the folded mountains and the coast is well suited to winter cereals, especially wheat, and to summer fruits such as grapes, peaches, plums, and apricots. (J. H. WN.)

III. THE PEOPLE

1. Ethnic Groups.—South Africa contains peoples of many diverse ethnic origins and differing cultures, languages, and forms of social organization. This complex situation may best be described historically, in terms of immigrations into the region.

Bushmen and Hottentots.—These, the surviving representatives of the original inhabitants of South Africa, are of non-Negro physical type, with languages which, though related to one another, are unrelated to any other language families. They are together known as Khoisan (*q.v.*). The Bushmen are, and would seem always to have been, hunters and gatherers, living a wandering life and divided into small isolated bands lacking any form of centralized chieftainship. Traces of their inhabitance, mainly in the form of rock engravings, show that they were once widespread

CONSTANCE STUART FROM BLACK STAR

BUSHMAN HUNTERS OF THE KALAHARI DESERT

throughout southern and central Africa; but they are now virtually confined to the more arid areas of South West Africa and Botswana. The Bushmen of what is now the Republic of South Africa were mainly killed, driven out, or absorbed by Negroes and whites. The Hottentots were pastoralists, keeping cattle and sheep, and occupied most of the southwestern corner of Africa at the time of the Dutch arrival at the Cape. Only the Nama Hottentots of South West Africa now form a distinct Hottentot-speaking group. Others have become part of various mixed-blood communities, described below. In the 1960s Bushmen numbered about 55,000 and the Nama about 25,000. (*See* further BUSHMAN; HOTTENTOT.)

Nguni.—The main element of the South African population consists of various Negro peoples speaking southern Bantu languages. They are, indeed, conventionally classified according to their linguistic affiliation and collectively referred to as Bantu for statistical purposes. The first Negro group to enter South Africa would seem to have been the cluster of tribes speaking Nguni dialects. They occupied what is now Natal and had covered much of the eastern Cape before the arrival of Vasco da Gama, and held the same areas when met by the Dutch and English in the 18th century. Nguni languages contain three of the so-called clicks (*c*, *q*, and *x*) of the Bushmen and Hottentots, and the Nguni tribes show some Hottentot physical characteristics; presumably they drove the Hottentots before them in their southern migrations and absorbed many of the Hottentot tribes.

The Nguni are usually divided into the southern Nguni of the Cape and the northern Nguni of Natal. The southern or Cape Nguni consist of several tribes, mostly living in the Transkei area: the Pondo, Thembu (Tembu), Xhosa, Bomvana, Mpondomise, and others, in all numbering well over 2,500,000. The northern Nguni include the Zulu, Swazi, Bhaca, Fingo, and others, and also total over 2,500,000, in Natal and the surrounding areas. As a consequence of the political upheavals of the early 19th century associated with the rise of the Zulu king Shaka (Chaka), several offshoots of northern Nguni moved northward: the Ndebele of the Transvaal, the Ndebele (Matabele) of Rhodesia, and the Ngoni of Malawi, Zambia, and Tanganyika.

All the Nguni of South Africa were traditionally organized into chiefdoms, reckoning descent patrilineally and observing strict patriarchy, and having economies of mixed agriculture and cattle raising. Some of them, particularly the Zulu and Swazi, established kingships and became important military nations in the 19th century. (*See* further NDEBELE; NGONI; NGUNI; SWAZI; ZULU.)

Sotho.—Behind the Nguni came the various Negro peoples speaking Sotho dialects, which are closely related to Nguni but lack the Hottentot-derived clicks. The Sotho-speakers consist of the southern Sotho, or Suto, of Lesotho; the western Sotho, or Tswana, of Botswana; and the northern Sotho of the Transvaal (the Pedi, Lovedu, and others). In the northern Transvaal are also the Venda, sometimes classified with the Sotho but usually counted as a distinct group. In their economy the Sotho peoples resemble the Nguni tribes, but they differ in certain other respects: some of them live in large towns rather than in the dispersed settlements of the Nguni, and they approve of marriage between cousins, whereas the Nguni prohibit it. They reckon descent patrilineally, like the Nguni, and are also organized into chiefdoms, often with rulers of marked sacred or even divine attributes. Some rulers, such as those of the Lovedu in the Transvaal, are women; they play a male role and "marry" "wives," whose children may inherit whereas any children of the ruler are counted as illegitimate. The rulers of the western and southern Sotho chiefdoms have greater secular and military power and resemble those of the Zulu and Swazi. (*See* further SOTHO; SUTO; TSWANA.)

With the growth of the diamond and gold industries and the development of cities such as Johannesburg and Kimberley there developed the system of migrant Bantu labour to the towns, mines, and white farming areas outside the Cape (in the Cape itself Coloured labour has always been predominant). This has led to an increasing Negro population in the towns, both purely migrant (*i.e.*, temporary) with its roots in the tribal reserves, and also fully urbanized and "detribalized," living permanently in the locations of the cities and towns. A good proportion of the temporary labour, especially that employed in mines, comes from outside South Africa, from Lesotho, Botswana, Portuguese East Africa, Rhodesia, Zambia, and Malawi. The permanent African urban population has tended to drop tribal customs and even tribal languages and to become a new amalgam with an urban, characteristically Western way of life, although economically it is an extremely depressed one.

See also AFRICA: *Ethnography (Anthropology): Southern Africa.*

European Intrusion.—The Europeans have lived in South Africa since the founding of Cape Town in 1652. Originally Dutch, the white population was first concentrated in the western Cape. The Dutch made early contact with the Hottentots and seem at first to have treated them with kindness and to have regarded them as of more or less equal standing (there was occasional intermarriage and much concubinage). With the extension of white farms along the Cape seaboard, whites came into direct competition with Hottentots over water and grazing; they drove some of them into the more arid regions to the north and made others into little more than serfs. The Dutch imported slaves, mainly from the East Indies and Madagascar. There was much miscegenation between whites (both Dutch and English) and slaves, Hottentots, and Bushmen, and the descendants of these various unions later became the Cape Coloured people. The Dutch, to show their allegiance to their new country, took the name Afrikaner.

The whites came into contact, and also into conflict, with Negroes on the eastern borders of the Cape during the 18th century. The ensuing "Kaffir Wars," fought between white and Negro farmers who desired the same lands and water supplies since both groups were mixed agriculturalists and cattle keepers, led to considerable tribal disruption and movement. This resulted in the founding of the Basuto nation, which was largely made up of refugees from elsewhere, and the appearance of the Fingo of the Ciskei from the remnants of broken Nguni tribes, and later of many small, racially mixed communities of white-Hottentot-Negro origin (the Griquas and others).

Asians.—The last main element in the South African population is Indian. Indians were brought to Natal in 1860 mainly as indentured labourers on the sugar estates in the humid coastal zone.

A century later they numbered nearly 400,000 in Natal, two-thirds of whom lived in Durban, with smaller communities elsewhere, mainly as traders. There are also a few hundred Chinese and smaller numbers of Mauritians, St. Helenians, and others, almost all in the towns.

2. Religions.—The traditional religious beliefs and practices of the peoples of South Africa vary widely. Those of the Bushmen and Hottentots were based upon worship of the moon and other heavenly bodies, although both peoples believed in an afterlife also. Among the Bantu-speaking groups the principal indigenous cults are those of the ancestors, sacrifice to them being made by the heads of lineages and clans. A high god was recognized but sacrifice was not made to him. Beliefs in witches and sorcerers were and are prevalent, witches being thought to be women throughout this region. In most of the states and large chiefdoms the ruler has important ritual duties at first-fruit ceremonies and other rites, which have both religious and political aspects. In some states the ruler has great sanctity: the king of the Venda is regarded as divine before his death, for example, and the queen of the Lovedu is recognized widely for her near divinity and power to control rain and fertility.

Christianity has become widespread among all the Bantu groups, the Methodist Church having the largest number of adherents. In most areas there are, besides orthodox mission churches, separatist churches led by Bantu priests, bishops, and archbishops (the latter often self-consecrated), who resent white control of most mission churches and regard themselves as prophets or messiahs. The separatist churches consist mainly of various "Zionist" churches, in which speaking with tongues and "rolling" are practised, and "Ethiopian" churches in which antiwhite, tribalistic, and nationalistic emphasis is strong.

Most Indians follow Hindu or Muslim rites. The majority of the Cape Coloureds are Christian, only the Cape Malays being Muslims. Among Europeans the most powerful churches are the Dutch Reformed churches. These churches, which have a mainly Afrikaner membership, accept racial segregation as divinely ordained, and as a result they have come under much criticism from Protestant churches outside South Africa. (*See* REFORMED CHURCHES: *History: The Netherlands: Former Dutch Colonial Areas.*) The majority of other Europeans belong to the Anglican, Methodist, Roman Catholic, or Presbyterian churches, and there is also a substantial number of Jews. None of these bodies accepts the views of the Dutch Reformed churches on racial segregation, and various individual members have expressed opposition to the South African government's racial policies.

3. Languages.—The two principal official languages are Afrikaans and English. At the 1960 census Afrikaans was given as first among 58% of the white population and English among 37.3%, but with instruction in both languages in schools, an increasing number of people are bilingual. (*See* also NETHERLANDIC LANGUAGE; SOUTH AFRICAN LITERATURE: *Afrikaans.*)

Africans speak various Bantu dialects; some, such as Xhosa (in the Transkei Bantustan), are accepted as official languages within the homelands and are used as vernaculars in education. A large number of Africans also speak English or Afrikaans, and a lingua franca known as Fanagolo is also used in the mining areas. (*See* AFRICAN LANGUAGES; BANTU LANGUAGES; BUSHMAN LANGUAGES.) (J. F. M. M.)

IV. HISTORY

Whether or not the Phoenicians sailed around Africa as claimed by Herodotus, southern Africa was unknown to the Greeks and the Romans and to Europeans before the 15th century. Then, largely as a result of the patronage of Prince Henry the Navigator, Portuguese mariners steadily pushed down the West African coast until in 1488 Bartolomeu Dias de Novais rounded the Cape of Good Hope and in 1498 Vasco da Gama, in a flagship of 120 tons, 80 ft. long, reached the objective, India. Thereafter the Portuguese gained maritime supremacy in the Indian Ocean and used it to exploit the Asiatic spice trade and, less effectively, the East African gold trade. But, though they colonized Angola and Mozambique, they made no settlements as far south as what is now the Republic of South Africa, regarding its resources as negligible and its inhabitants as too primitive for commercial or evangelical effort. Throughout the 16th century, therefore, though South African waters were often traversed by Portuguese fleets, the only civilized people who spent much time ashore were the survivors of the many ships that were wrecked on the coast.

A. DUTCH FOUNDATIONS

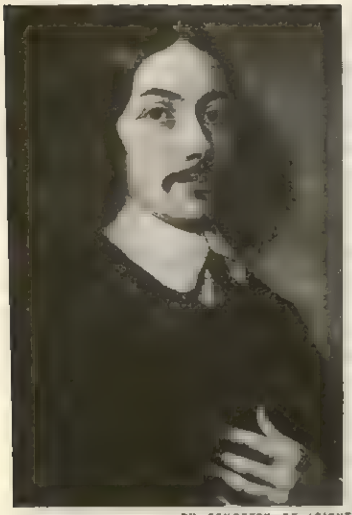
1. Trading Companies.—By the end of the 16th century Dutch and English seamen had also begun to trade with Asia by the Cape route. They found it desirable to pause for refreshment (the death rate on the long voyage being often as high as 50%), and during the first half of the 17th century they usually stopped at St. Helena, the Cape, or Mauritius. In 1615 the English tried vainly to form a settlement at the Cape with ten felons reprieved from the hangman's noose, and five years later two English captains made the empty gesture of annexing all Africa for James I; but it was St. Helena that eventually became the main port of call for the English company.

Meanwhile the Dutch East India Company (*q.v.*) outstripped all rivals and obtained a virtual monopoly of the East Indian spice trade. For several decades Dutch ships made a practice of putting into Table Bay to take in fresh water, to barter with the Hottentots for meat, and to find the latest information about the affairs of Europe or Asia in dispatches they left one another under inscribed stones. Then in 1647 Leendert Janssen was shipwrecked in Table Bay with the crew of the "Noord Haarlem," and after his return to the Netherlands he presented a report advising the company to found a permanent refreshment station at the Cape. Largely because the Anglo-Dutch War of 1652–54 was imminent, the directors eventually agreed; three ships were to take out building materials, seeds, and implements, and 90 men were to build a fort and develop a vegetable garden.

2. Jan van Riebeeck.—To command the expedition the directors chose Jan van Riebeeck (*q.v.*), a doctor by training, who had already had six years of commercial experience with the company. He landed at the Cape on April 7, 1652, and remained ten years, during which time droughts, floods, and pests, indiscipline among his subordinates, and thefts by the Hottentots often brought the settlement to the brink of disaster. But it survived; a timber-and-sod fort was built, the coastline was charted, the interior was explored, and a belt of land extending about eight miles from Table Bay to Wynberg was brought under cultivation.

However, the Cape did not become the simple outpost the directors had had in mind. At that time Hottentots, pastoral nomads loosely organized in small tribes, occupied most of the coastal regions of South Africa as far east as the Great Fish River. The Cape Peninsula had been used by three such tribes, who regarded the Dutch as intruders in their domain, especially when it became apparent that they were not birds of passage but were building fortifications and extending their area of cultivation. The Dutch bartered with the Hottentots for sheep and cattle and from time to time the Hottentots stole them back again. Van Riebeeck calculated whether he was strong enough to use force, but when the directors cautioned him to do no such thing he fell back on the idea of confining the settlement within a palisade. Yet even at this early stage in South African history it was not possible to keep the races completely apart, because the Dutch continued to barter with the natives.

Van Riebeeck also initiated two experiments which had far-reaching consequences. At first all the work of the station was done by the company's servants, but in 1657 a few slaves were imported and more came in 1658 and thereafter. The second experiment started in 1657 when the company, hoping it would save money if grain were grown and stock bred by unpaid freemen instead of by paid employees, freed nine married men from their contracts and gave them 30-ac. farms along the Liesbeeck Valley at Rondebosch. These people, who were known as burghers, were to produce grain and stock and sell them to the company at agreed prices. So Van Riebeeck left behind him an embryonic colony of settlement which used slave labour and was confronted with a "native problem."



BY COURTESY OF (RIGHT) THE SOUTH AFRICAN INFORMATION SERVICE, (LEFT) THE GRANGER COLLECTION

(LEFT) JAN VAN RIEBEECK, LEADER OF THE FIRST WHITE SETTLEMENT IN SOUTH AFRICA; (RIGHT) AN ASPECT OF CAPE TOWN AS PAINTED ABOUT 1720 BY AN UNKNOWN ARTIST

who recalled Van der Stel in 1707. But the underlying cause of the discontent—the commercial policy of the company—was not remedied.

4. Evolution of the Afrikaner People.—The company, probably convinced that white settlement led to political agitation, had no vision of a New Netherlands in South Africa and sponsored no immigration schemes after the time of the Van der Stels. Nevertheless, during the 18th century a New Netherlands of a sort was arising from the materials present. The white population grew, mainly by natural increase, to about 15,000 in 1795, by which time they regarded South Africa as their only home and spoke a language, Afrikaans, which deviated from the language of the Netherlands. Those who lived in Cape Town—the only port and the only real town in the colony—were mostly traders and innkeepers. In the southwestern part of the colony, near Cape Town, were the grain and wine farmers, some of them proprietors of large estates run by slave and Hottentot labour. Beyond them were the trekboers, about half the total white population.

The trekboers were seminomadic, many of them completely nomadic, pastoral farmers. Most of the land they occupied was unsuitable for cultivation; moreover, the market for agricultural produce was glutted and slaves did the skilled work of the colony. There was, therefore, nothing to keep the increase of the white population in the southwestern Cape and much to encourage them to disperse and become self-sufficient pastoral farmers.

The way was paved by W. A. van der Stel, who, unlike his father, allowed burghers to concentrate on stock farming. Within a few years it became possible for any burgher to take occupation of 6,000 ac. or more of land and treat it as his property, paying the company a small annual licence. The result was a continuous expansion of the frontiers of white settlement. In the north the trekboers were slowed up by aridity and finally stopped near the Buffels River about 1760. In the east they advanced along either side of the arid Great Karroo until in the 1770s the two streams of pioneers began to mingle beyond it in the vicinity of what became Graaff-Reinet, about 400 mi. (640 km.) from Cape Town.

Thus a few thousand white persons scattered over an area about twice as large as England and about the size of Colorado. Their simple needs were met by their stock and by hunting and by traveling traders who bought their sheep and cattle for the Cape Town market and sold them a few imported goods. The company did little for them beyond establishing courts of landdrosts and heemraden at Swellendam (1745) and Graaff-Reinet (1785). From time to time officials expressed concern that the isolation of the trekboers was causing them to degenerate. But although all the trekboers were extreme individualists and some were ruffians, most of them contrived to preserve a sound domestic morality, a smattering of literacy, and a respect for their religion, a rather strait Calvinism.

5. Slaves, Hottentots, and Bushmen.—During the 18th century the slaves, the Hottentots, and some of the Bushmen were beginning to interbreed with one another and with Europeans to produce the community now known as the Cape Coloured people. Although few slaves were imported, the slave population outstripped the white to number nearly 17,000 in 1795. Negroid types from the west and east coasts of Africa predominated, with Malays from the East Indies forming an important minority. There was a considerable amount of extramarital miscegenation between white men and slave women. Most of the slaves were the property of the agricultural farmers, for whom they formed the main labour supply. Others were owned by the company and the

3. Immigration and Expansion.—In 1662 the Cape settlement numbered about 250 white persons, of whom nearly half were company servants, and in the next few years there was little increase. But during the governorships of Simon van der Stel (1679–99) and his son W. A. van der Stel (1699–1707) the company made its one serious effort to encourage immigration. In 1707 a census showed a burgher population of 1,779 men, women, and children, owning 1,107 slaves. This was a slow rate of progress when compared with that of the English colonies in North America.

Nevertheless, the modern Afrikaner people are descended for the most part from those who were enumerated in 1707. These were company servants who had taken their discharge at the Cape and people who were sent out to settle. Most of them were of Dutch and German stock. There was also a small but significant group of fewer than 200 French Huguenots who, after the revocation of the Edict of Nantes in 1685, went to the Netherlands and then were sent to the Cape. As a matter of policy the company scattered the Huguenots among the other settlers, and within little more than a generation they became fully assimilated, discarding the French language and even pronouncing their names in the Dutch manner.

The area of settlement expanded with the population—to Stellenbosch beyond the sandy Cape Flats (1679) and then to the Berg River Valley. To meet the needs of local administration a general purposes official (landdrost) was appointed to Stellenbosch in 1685; sitting with four local burghers (heemraden), he was given jurisdiction in minor civil cases. Nearly all the company servants, however, lived in Cape Town, where the governor and his chief subordinates formed a Council of Policy which issued regulations for the colony, subject to the overriding authority of the governor general and council of the Indies in Batavia and the directors in the Netherlands.

From the first the burghers had fretted at many of the regulations, which imposed restrictions and taxes on internal trade; for example, the rights to deal in much local produce, including cattle, were auctioned annually to contractors, as well as the rights to retail imported goods. Furthermore, by the end of the century the Cape was producing more wine, brandy, and grain than was consumed locally and by passing ships, and there was little opportunity for export.

What was particularly galling to the burghers was the tendency of the officials to farm and trade on their own account, using their authority to make sure that their own produce did not remain unsold. This led to an outcry against the governor, W. A. van der Stel, who embarked on large-scale farming operations and cornered the market so successfully that some malcontents, including the Huguenot diarist Adam Tas, sent a petition to the directors,

Cape Town burghers, a few by the trekboers. The treatment of the slaves, which had at first been fairly mild, tended to deteriorate, and the 1754 slave code was a stiff one.

The nearest approach to a Hottentot war had taken place in the 1670s. But it was smallpox that took the heaviest toll of the Hottentots, especially a shattering epidemic in 1713. After that, as the trekboers advanced into their territories, the surviving Hottentots lost their land and their cattle—their only means of an independent existence. Many were reduced to a status not unlike serfdom, forming the main labour supply of the trekboers, whose simple demands they were able to satisfy. Others withdrew beyond the frontiers of white settlement to maintain a more or less independent existence until the next century.

THE BETTMANN ARCHIVE

HOTTENTOTS: A LATE 18TH-CENTURY ENGRAVING

There was a certain amount of miscegenation between white men and Hottentot women, although intermarriages had been unlawful since 1685. The offspring were usually disowned by their fathers and became known, bluntly, as Bastaards; some entered into service, others retreated before the advancing trekboers, leading trekboer lives themselves.

The small Bushmen were still more primitive than the Hottentots. Before white settlement began they had been driven into the more arid and mountainous parts of South Africa by the Hottentot and other African tribes. But, though every man's hand was against them, they contrived to make hit-and-run raids to get sheep and cattle for food, and, if cornered, they were able to kill human beings with their poisoned arrows. As the trekboers in turn began to enter Bushman country and to suffer from their raids they organized Boer commandos to hunt them. Toward the end of the 18th century several Bushmen bands made a prolonged stand, operating from mountain fastnesses along the northern fringes of the area of white settlement; but the commandos gradually cleared them out, killing 2,500 Bushmen and capturing 650 in the decade ending in 1795. Those captured were children, who were taken into service.

Their experience with slaves, Hottentots, and Bushmen had important and enduring effects on the racial attitudes of the Afrikaner people. Most of the nonwhites they came into contact with were at so low a cultural level that the Afrikaners tended to think of themselves as innately superior. Their response was not merely hostile, however, because they all—Capetonians, agriculturalists, and trekboers—came to depend on the use of nonwhite servants.

6. African Opposition and Economic Discontent.—Before the last quarter of the 18th century the trekboers had not been seriously impeded by human obstacles. Then, however, they came up against formidable opposition.

Bantu-speaking tribes had occupied the eastern half of South Africa for several centuries. They were more numerous than the Hottentots. They had a more complex social and political structure. They cultivated the soil as well as hunting game and herding cattle. They made iron weapons and tools. South of the Limpopo River were two main groups of Bantu-speaking peoples: the Sotho, who lived on the plateau; and the Nguni, in the coastal belt. The westernmost Nguni tribes slowly expanded westward as population increased and tribes split, but the trekboers moved toward them more rapidly. Early in the 18th century Boer hunters began to make contact with the Nguni and bartered with them for cattle and ivory. The company vainly tried to prevent such contacts and delay the convergence of the Boers and the Nguni by issuing proclamations prohibiting barter and defining limits beyond which the Boers were not to go. When the governor, J. van Plettenburg, toured the frontier in 1778 he found that Boers were already intermingled with Africans in the vicinity of the Great Fish River.

A long series of frontier "wars" followed—basically struggles for possession of the land. The first fighting took place in 1779–81 and was sufficient to show the Boers that they faced tough opposition. They therefore appealed to the company for aid; although a landdrost, M. Woeke, was appointed to Graaff-Reinet in 1785, no troops were sent. Woeke's life was soon made intolerable by the Boers, and in 1793 he was superseded by H. C. D. Maynier. Further fighting broke out in that year and again the result was inconclusive. The Boers were disgruntled. For nearly a century they had been left by the company to make their own terms with man and nature, and when at length they had asked for help all they received was a government official who not only failed to defeat the Nguni but also allowed Hottentots to come to his court with complaints against them. In 1795, on the eve of the British conquest of the Cape, they drove out Maynier and declared Graaff-Reinet to be a republic. But the name "republic" was a euphemism: in fact there was anarchy at Graaff-Reinet. Similar events took place at Swellendam, where another "republic" came into being.

Meanwhile there was trouble in the southwestern part of the colony also. The company had maintained rigorous commercial restrictions, together with a system of government that gave the colonists practically no voice in the determination of policy. The trekboers had managed to escape most of the effects, but the restrictions had always borne heavily on the agricultural farmer who had produce to sell and on the Cape Town man who lived by trade. In the 1770s, which were lean years, the discontent came to a head with the organization of the Cape Patriots movement, which had some connections with the anti-Orange Patriot Party in the Netherlands. A petition was drawn up criticizing many of the officials and asking for full burgher representation on the Council of Policy and the right to trade freely throughout the company's possessions. When it was laid before the directors in Amsterdam, their only response was to dismiss the official who was most roundly criticized—the fiscal, W. Boers.

In 1784 a second petition was taken above the heads of the directors to the States-General of the Netherlands. This time the burghers were given equal representation with officials on the Court of Justice (though not on the Council of Policy) and the right to trade with the company's possessions—a right that was nullified by the conditions that were attached. By then, however, the disaffection had subsided because the American Revolutionary War had brought a large French garrison to Cape Town to help the Dutch to defend it against the British, and the garrison provided an abnormally large market for Cape produce and brisk business for the traders and innkeepers. In the early 1790s bad times came again as the company, trying desperately to stave off bankruptcy, made a final effort to make the colony pay its way. The garrison was reduced, public works were suspended, and—the last straw—new taxes were imposed. So, when the British invading force arrived in 1795, it found depression in the west and rebellion in the east. The company had never done much for the white colonists and still less for the nonwhite peoples.

B. South Africa Divides (1795–1870)

1. British Conquest.—In the course of the Napoleonic Wars, the Cape was captured by a British naval and military force in September 1795, nominally on behalf of the prince of Orange, who had taken refuge in England from the Dutch republicans. In their struggle with France the British considered it essential not to let the Cape fall into enemy hands, and until the Treaty of Amiens a hold was kept on it for strategic reasons. The British tried to conciliate the Afrikaners, and by abolishing the restrictions on internal trade and maintaining a large garrison they caused an economic revival in the southwestern part of the colony. On the eastern frontier, on the other hand, the British were no more successful than their predecessors had been. Although the republics of Swellendam and Graaff-Reinet soon submitted to the new government, anarchy developed in Graaff-Reinet again in 1799, after the arrest of a prominent trekboer, A. van Jaarsveld, on a charge of forgery. Not only the Xhosa but also many of the Hottentot servants of the Boers made the most of the opportunity

created by the divisions among the whites and caused havoc as far west as Knysna. The British general F. Dundas patched up a truce; but H. C. D. Maynier, appointed resident commissioner of the two eastern districts, failed to satisfy the trekboers, who rebelled again in 1801, when once again their Hottentot servants joined with Xhosa tribesmen to harry the farms over a wide area.

The eastern districts were therefore in turmoil when Britain gave up the Cape under the terms of the Treaty of Amiens (1802). By this time the company was defunct, and the Dutch government —the Batavian Republic organized by the French in 1795 after their conquest of the country—succeeded to its charge. J. A. de Mist, the commissioner-general, and Gen. J. W. Janssens, the governor, tried to restore the morale of the Boers and showed a considerable understanding of the problems of the country; but these men did not stay long enough to consolidate their reforms, for in 1806 the British sent out another force to recapture the Cape from Napoleon's Dutch allies. Janssens lacked the means to put up much resistance and once more the colony passed into the hands of the British, whose title was confirmed in 1814 as part of the general peace settlement.

2. British Policy, 1806–36.—Until 1823 British policy was cautious and conservative. The governor had autocratic powers, but the Afrikaners were used to that. Moreover, their Roman-Dutch law was retained, and local administration remained as of old in the hands of landdrosts and heemraden, most of them Afrikaners. These were comparatively prosperous years. The southwestern farmers profited from their access to British markets, where their wine sold well thanks to a substantial tariff preference. Elsewhere, however, extensive pastoral farming remained the norm. Nevertheless, the British did introduce some changes in these years. They appointed more landdrosts. In 1809 they promulgated a code for the treatment of Hottentot servants, who were to be employed only under written contracts registered at a landdrost's office and were given legal protection against ill treatment; on the other hand, they were not to be allowed to leave their employer's farm without a pass signed by the employer. From 1811 onward high court judges, who had previously sat only in Cape Town, made annual circuits to hear cases in all the districts.

Mild though these reforms were, they caused trouble. There was much grumbling in 1812 when the judges on circuit in the eastern districts tried a number of Afrikaners on charges of ill treating their Hottentot servants. Three years later a trekboer, F. C. Bezuidenhout, opened fire on a party that had come to arrest him for repeatedly ignoring his landdrost's orders to answer a charge of cruelty; in the skirmish Bezuidenhout was killed, whereupon his brother proceeded to organize opposition to the government; but the Slachter's Nek Rebellion soon ended when about 60 rebels were rounded up and tried, and five ringleaders were hanged.

The British also brought superior force to bear against the Xhosa on the eastern frontier and thus started the process of the conquest of the African tribes. In 1811 British regular troops and Boer commandos drove the Xhosa back to the eastern side of the Fish River, and in 1819 to the eastern side of the Keiskama.

In 1820, 5,000 British settlers were brought out and placed on 100-ac. lots in the Zuurveld, on the western side of the Great Fish River. The 1820 settlers did not, however, form the human barrier that was intended, because the land was not suited to agriculture; within a few years most of them had abandoned their lots and become townsmen in Port Elizabeth and Grahamstown. Others became traders among the African tribes to the east. Those who stayed on the land eventually made good by producing wool for export to England, especially when large farms came on to the market at the time of the Great Trek. This was the first subsidized immigration scheme since the 17th century, and the 1820 settlers were the first white immigrants who were not assimilated by the Afrikaner people.

When they had got their bearings the 1820 settlers were dismayed to find that the legal system of the colony was alien to them, the judges were officials without any particular legal training, and Lord Charles Somerset, the governor from 1814 to 1826, was an autocrat who made it impossible for them to publish a newspaper. Their agitation for British liberties and institutions evoked some response. The Charter of Justice of 1827 created a Supreme Court of qualified judges with security of tenure, abolished the heemraden, and introduced English rules of procedure and evidence, including the jury system, while it left untouched the Roman-Dutch substance of the law. In 1834 an Executive Council of officials and a Legislative Council of officials and nominated nonofficials were established. By that time the freedom of the press had been won, English had become the official language of the courts, and British teachers had been imported to start village schools in which English was the medium of instruction.

During these years South Africa was attracting the attention of the British humanitarians or evangelicals who were striving to free the nonwhite populations of the colonies from their legal disabilities. They were supplied with severe criticisms of South African conditions by John Philip, South African superintendent of the London Missionary Society, which had established a number of mission stations up and down the country. Philip reached the conclusion that the Hottentot code of 1809, with its stringent pass regulations, was unjust; in 1826 he returned to England to appeal to the government and the British public, and in 1828 the House of Commons passed a resolution for the emancipation of the Hottentots. Seeing the trend of affairs, Gen. (afterward Sir) Richard Bourke, the acting governor, had already passed an ordinance, no. 50 of 1828, which abolished the pass system and gave "free persons of colour" complete liberty of movement. Meanwhile, with their eyes focused primarily on the West Indies, the British government had been insisting on improvements in the treatment of slaves; and in 1833 the reformed Parliament passed the Emancipation Act under which all slaves in the colonies became free after a period of apprenticeship, and £20,000,000 was voted as compensation to their owners. When their period of apprenticeship ended in 1838 the former slaves in the Cape Colony stepped into the position of other "free persons of colour." Thereafter the emancipated slaves and Hottentots—the Cape Coloured people—became a rural and urban working class in the Cape Colony.

Meanwhile frontier trouble had flared up again. Unrest had developed among the border Nguni tribes for various reasons, including the frequency of military raids on their villages made in reprisal for the theft of stock from white farmers. In 1834 Gen. Sir Benjamin D'Urban (*q.v.*) arrived as governor with instructions to devise a more equitable policy, but he did nothing about it until large bodies of Africans invaded the colony and did serious damage. D'Urban then reasserted British military superiority and annexed the land up to the Great Kei River, from which most of the Africans were to be expelled (May 1835). But he found it impossible to enforce the expulsion, and the colonial secretary, Lord Glenelg, disapproved; consequently, in 1836 the territory was disannexed and an attempt was made to pacify the tribes by making treaties with their chiefs. By that time, however, the frontier was no longer a clear line of division between the races; white traders and missionaries were working among the tribes to the east of it, and Africans were working on white farms to the west.

3. The Great Trek.—For several generations the trekboers had been left more or less to their own devices. Now, under an alien government actuated by liberal ideals which they did not comprehend, many of their institutions were being transformed. They were short of labour and they found it difficult to comply with the regulations and get the compensation money for their slaves; their property was being pilfered by wandering Hottentots and they suffered further losses during the African invasion in 1834. Behind all these things they saw the hand of missionaries, who, they considered, misrepresented them in England. The reversal of D'Urban's frontier policy was the last straw that made many of them decide to throw off British dust and find a new home where they could, in the words of Piet Retief (*q.v.*), their ablest leader, "preserve proper relations between master and servant." Later, Anna Steenkamp recorded that the British had placed their slaves "on an equal footing with Christians, contrary to the laws of God and the natural distinctions of race and religion, so that it was intolerable for any decent Christian to bow down beneath such a

yoke; wherefore we withdrew in order thus to preserve our doctrines in purity." Imbued with this spirit the *voortrekkers*, about 12,000 Afrikaners, men, women, and children, left the colony with their sheep, their cattle, their ox wagons, and their Coloured servants between 1835 and 1843.

In the previous two decades there had been widespread destruction and dislocation among the African tribes, caused by the Zulu under Shaka, and their offshoot, the Ndebele or Matabele, under Mzilikazi (Moselekatse). (*See* ZULULAND.) By the time of the Great Trek two areas seemed suitable for white settlement—Natal, south of the Tugela River, and the High Veld, on either side of the Vaal. But appearances were deceptive, for these two areas were kept denuded by Zulu and Ndebele impis (regiments). The first *voortrekkers* made for the High Veld, where they were attacked by the Ndebele, whom they routed in 1837. Most of them then decided to settle in Natal. Piet Retief and a pioneer group went to the kraal of Dingane (Dingaan), Shaka's successor, to negotiate for a cession of land; and there, in February 1838, he and 70 Boers and 30 Coloured servants were treacherously massacred, while another 300 Boers, mainly women and children, and 200 Coloured servants, were killed in upper Natal. On Dec. 16, 1838, however, Andries Pretorius gained a decisive victory over the Zulu at Blood River. Most of the *voortrekkers* then proceeded to stake out farms in Natal. Border troubles ensued, and when in 1840 a Boer commando expedition made a sortie to the south against the kraals of a chief named Ncaphayi (Ncapaai), his neighbour Faku, who had a treaty with the British, appealed for aid.

Previously the British had been undecided what to do about the *voortrekkers*; the Cape of Good Hope Punishment Act of 1836 had made them liable, as British subjects, to trial in British courts for crimes committed south of latitude 25° S, but little had been done to make it effective. Then, however, anxious lest the activities of Natal commandos lead to disturbances on the Cape frontier, the governor, Sir George Napier, sent a small force to Natal, which, after some fighting, became British territory in 1843. Most of the *voortrekkers* who had settled in Natal then inspanned their oxen again and trekked back to the High Veld, north of the Vaal River, where they proved to be immune from further British attention for a generation.

Between the Orange and the Vaal, however, the British were drawn in for a while. There was a racial medley in that region: Griquas (Hottentot-European half-castes), who had lived north of the Orange River for several decades; Africans, survivors of the Ndebele devastation of the High Veld, who had been rallied by Moshesh (*q.v.*, or Moshweshwe), a Suto, or Sotho chief, near the Caledon River; and Afrikaners. The British had made a treaty with the West Griqua chief, Andries Waterboer, in 1834, and they made treaties with the East Griqua chief, Adam Kok III, and with Moshesh in 1843, hoping to use them to keep the peace along the Orange River. Trouble followed when Kok, in accordance with his treaty, tried to hand an Afrikaner over to the Cape authorities for trial under the Punishment Act. The Afrikaners took up arms and were dispersed by troops from the Cape at Zwartkoppies (1845). Two years later Gen. Sir Harry Smith became governor of the Cape Colony and British high commissioner in South Africa. An optimist, he believed that the South African imbroglio would be pacified if the area of British authority was extended. Accordingly, after overcoming further African resistance on the eastern frontier of the Cape, he annexed the land up to the Great Kei River as the province of British Kaffraria (1847) and the land between the Orange and the Vaal as the Orange River Sovereignty (1848). The colonial secretary, Earl Grey, accepted these annexations most grudgingly.

Humanitarian influence was waning in Britain and the main concern of the Colonial Office was to cut down expenses. Therefore, when further fighting broke out on the eastern frontier and similar difficulties developed with Moshesh in the Orange River Sovereignty, the British government decided to reduce its commitments in South Africa by recognizing the independence of the *voortrekkers*. This was done in two stages. In 1852 the Transvaalers were granted "the right to manage their own affairs without any interference on the part of the British government" in a convention signed at the Sand River; and in 1854 similar arrangements were made with the Afrikaners of the Vaal-Orange area at Bloemfontein.

South Africa was thus divided into three camps: Afrikaner republics; British colonies; and still-independent African societies.

4. Afrikaner Republics.—At the time of the Bloemfontein convention there were about 15,000 white persons engaged in pastoral farming in what then became the Orange Free State. They soon agreed on a rigid constitution, which vested legislative power in an elected council (*Volksraad*), executive power in an elected president—the voters being the white male adults—and local administration in landdrosts and heemraden on the old Cape model. The East Griqua question was settled in 1861 when Adam Kok sold out his remaining land rights in the Free State and trekked with his people to found a new Griqualand East nearer the coast (*see* GRIQUALAND EAST AND GRIQUALAND WEST). The Suto question was more difficult. The British had abandoned the sovereignty because they shirked the expense of controlling the brisk rivalry between the Afrikaners and the Suto for the Caledon River valley, which included some of the best arable land in southern Africa.

When fighting broke out in 1858 the Suto outmaneuvered the Free Staters, who were glad to accept the mediation of the high commissioner Sir George Grey (first convention of Aliwal North). The Free Staters, conscious of their weakness, then tried to unite with the Transvaal but were stopped by Grey, who threatened to withdraw the recognition of their independence and advised them to federate with the Cape Colony; yet when they expressed a desire to do so, the British government refused. Grey considered that a federation, under the crown, of all the colonies and republics in South Africa would be in the general interest. The British government, however, was averse to any extension of its area of responsibility. Further fighting started in 1864; this time the Free Staters were more successful and were able to dictate stringent terms, by which Moshesh lost most of his arable land (Treaty of Thaba Bosiu, 1866). But the peace was not kept and Moshesh asked Britain to annex Basutoland. This was done in 1868 and the next year the frontier line between the Free State and Basutoland was agreed upon (second convention of Aliwal North; *see* also LESOTHO).

The intervention of the British preserved for the Suto people more land than had been left to them in 1866; but it gave serious offense to the Free Staters, depriving them of the fruits of their victory. Thereafter the Free State, its frontiers pacified and absolved from the responsibility of administering a large number of Africans, became what Lord Bryce once described as a model republic, under the wise leadership of J. H. Brand, president from 1864 to 1888 (*see* BRAND, SIR JOHANNES HENRICUS). The Cape Colony took over Basutoland in 1871, but later got into difficulties in trying to force the Suto to forfeit their arms and was glad to hand it back to Great Britain in 1884.

Meanwhile the *voortrekkers* north of the Vaal River, numbering perhaps 22,000 at the time of the Sand River Convention, preserved their old trekboer mode of life. It was not until 1857 that most of them overcame their factional disputes and united to form the South African Republic under the presidency of M. W. Pretorius, son of the victor of Blood River (*see* PRETORIUS). Their constitution, which created institutions similar to those in the Free State, frankly stated that "The people desire to permit no equality between coloured people and the white inhabitants, either in church or state." Otherwise it was an ambiguous document, and from the first the *Volksraad* ignored any restraint but that of force. In 1863 there was further factional fighting; and Boer expansion frequently led to disputes with African tribes, the weaker of which were broken up, the remnants becoming squatters and servants under white landowners.

5. British Colonies After the Great Trek.—Not more than a quarter of the Afrikaners had left the Cape Colony during the Great Trek, though others went north in later years. Those who remained gradually became accustomed to the more equal order, and in the course of time a liberal tradition developed in the colony, in contrast with the illiberal tradition of the republics.

When the colony received representative government in 1853, the only franchise qualifications were low economic ones, irrespective of race or colour; but most of the Coloured people were unable to qualify and the vast majority of the electorate were white men. By that time the loss of population had been offset by further British immigration; and the decline in viticulture caused by the removal of British tariff preferences was remedied by an increase in the production of wool for export.

In British Kaffraria the high commissioner, Sir George Grey, tried to achieve quick results from a policy of civilizing the Africans by encouraging trade, mission schools, medical services, and public works, by bringing in white settlers, and by using white magistrates to undermine the authority of the chiefs. There was a reaction in 1857, when the Africans destroyed their own stock and crops in the superstitious belief that the white man would then vanish from the country. The result was catastrophic: thousands starved to death and emaciated survivors poured into Cape Colony in search of work. In 1865 British Kaffraria was incorporated in the colony. Soon afterward the British government urged Cape Colony to assume full responsibility for its own affairs, and in 1872 a responsible government bill was carried and J. C. Molteno became first prime minister.

British immigrants had settled in Natal, so that its white population became predominantly British and crept up to 9,000 in 1856, when representative institutions were established, and to 50,000 in 1893, when responsible government was obtained. Mixed farming was practised inland and sugar was grown in the subtropical coastal belt.

One result of the defeat of Dingane was an influx of Africans from Zululand into Natal, many of them returning to the region from which they had formerly been evicted by Shaka. Thus the African population rose steeply from about 20,000 in 1840 to nearly 500,000 in 1893. They were handled by Sir Theophilus Shepstone (*q.v.*), the son of a missionary who had come to South Africa with the settlers in 1820. He placed most of the Africans in a number of reserves or locations, comprising about one-seventh of the total area of the colony. Their tribal laws and customs were maintained and they were able to preserve their tribal economy for another generation, when they began to suffer from land shortage. Africans subject to tribal law were not eligible for the franchise, but in 1864–65 laws were passed which enabled Africans to apply to be exempted from tribal law and, seven years later, for the franchise. However, the regulations were such that few became exempted and hardly any became voters.

The colonists were critical of Shepstone's policy, mainly because it did not make the Africans work for them. The coastal sugar planters, in particular, were short of labour, and it was to help them that Natal began to import Indian labourers in 1860. By 1866, 6,000 had arrived, and when their five-year contracts expired most of them chose to stay in Natal, as they were entitled to do. In 1872 the Indian government prohibited further emigration because some of the Indians had complained of ill treatment; but the migration was resumed on a large scale, with a heavy government subsidy, in 1874, and by the end of the century the Indians outnumbered the whites in Natal.

C. Through War to Union (1870–1910)

1. Diamonds and Gold.—After 1870 the South African economy was rapidly transformed. Previously South Africa had been an economic backwater, with most of its inhabitants, whites and nonwhites, engaged in inefficient near-subsistence farming; and it had lacked the means to attract the capital and the skilled personnel to create the facilities of a modern country. In 1867 alluvial diamonds were found along the Orange and the Vaal rivers; in 1870 the dry diamond diggings began to be worked at Kimberley; and in 1886 the gold rush to the Witwatersrand began to eclipse all previous gold rushes. The effects were remarkable. The sum of South Africa's imports and exports rose from £49,000,000 in the decade 1861–70 to £128,000,000 in 1871–80, to £179,000,000 in 1881–90, to £357,000,000 in 1891–1900, and to £700,000,000 in 1901–10. In the last of these decades gold (59%) and diamonds (19%) accounted for 78% of South Africa's exports; and by 1910, £121,000,000 had been invested in the Witwatersrand gold-mining industry and dividends totaling £77,000,000 had been paid by it.

Immigration raised the white population from about 328,000 in 1875 to 1,117,000 in 1904. Railway construction was even more striking: in 1870 there were only 69 mi. (111 km.) of railway track in all South Africa; by 1886 there were 1,800 mi. (2,900 km.) and the line from Cape Town had reached Kimberley; by 1895 there were 3,600 mi. (5,800 km.) and Johannesburg was connected with five ports—Cape Town, Port Elizabeth, East London, Durban, and Lourenço Marques (Portuguese East Africa).

Thus South Africa at last entered the world economy and acquired a special place in it as the source of about a third of the world's annual supply of gold and of more than half its diamonds.

The control of these great industries became concentrated in a few hands. The digger phase on the diamond fields was short-lived; companies forced out individuals and then the companies amalgamated until in 1891 De Beers Consolidated Mines controlled the entire South African diamond industry. The digger phase on the gold fields was even shorter, but there the process of concentration never reached quite the same finality; companies became organized into groups or corporations, and the groups became associated in the Chamber of Mines for certain purposes only, notably for the recruitment of African labour. Thus great financial power came to be exercised by a few men, above all by Cecil Rhodes, who went to South Africa for his health in 1870 and became the most successful of all the mining financiers, controlling both De Beers and the Consolidated Gold Fields, one of the strongest gold corporations (*see* also Rhodes, Cecil John).

The skilled work in the mining industries was done by whites, mainly immigrants at first, who drew high wages. The unskilled work was done by low-paid Africans who went to the mines from all over southern Africa, especially from Portuguese East Africa, to work for limited periods during which they lived in closed compounds, separated from the ordinary life of the community. In 1898, for example, the Witwatersrand gold-mining industry employed 9,476 whites at an average monthly wage of £26 and 67,797 Africans at an average monthly wage of £2 9*s*. Previously many Africans had been employed as farm labourers in return for squatting rights or low wages. Now the agrarian pattern of race relationships was being adapted to the mining industries, which, having a voracious appetite for labour, were giving a distinct impetus to the long-drawn-out process of the disintegration of tribalism.

The discovery of diamonds led to a serious controversy. The Transvaal claimed part of the diamondiferous area and the Orange Free State claimed the rest of it, while David Arnot, a white attorney, claimed it all on behalf of his client Nicholas Waterboer, the chief of the West Griquas. Arnot managed to persuade the British Colonial Office that the Griquas had the best case; therefore when a new high commissioner, Sir Henry Barkly, reached South Africa in January 1871 he had instructions to take a strong line. Barkly persuaded M. W. Pretorius, the Transvaal president, to submit his case to arbitration by R. W. Keate, the governor of Natal. When Keate discovered that Pretorius had unwittingly placed great reliance on a forged document, he decided against him. Although this award did not directly affect the Free State claims, which were the strongest, Barkly, failing to understand their merits, annexed to the crown the entire area claimed for Waterboer in the same month (October 1871). Five years later a land court decision exposed the fallacies in Waterboer's claim to sovereignty over the diamond fields; whereupon J. H. Brand, the Free State president, went to London and exacted £90,000 compensation from the imperial government. In 1880 Griqualand West was incorporated in the Cape Colony.

2. Annexation and Retrocession of the Transvaal.—Lord Carnarvon, colonial secretary in Disraeli's 1874 ministry, hoped that the South African states and colonies might unite in a self-governing federation under the British crown. The following year he summoned a conference to discuss the project in London, but it was a failure. The Free State, smarting under the recent annexations, would have nothing to do with the project; nor would

ZULU WARRIORS IN BATTLE DRESS (1888)

the Cape, whose ministers' dignity had been ruffled by the conduct of the historian J. A. Froude, who had toured the colony on behalf of Carnarvon urging federation. Federation from the south having failed, Carnarvon turned his attention to the north and found that the South African Republic was ripe for plucking.

That republic, unlike the Free State, had never acquired stability. Pretorius was bundled out of the presidency after the annexation of Griqualand West, and the Transvaalers chose as his successor Thomas François Burgers (*q.v.*), a Cape colonial preacher of the Dutch Reformed Church. But in Burgers they had more than they had reckoned for; he was critical of Transvaal backwardness and proposed to remedy it by social, educational, and religious reforms. He also borrowed money, intending to build a railway to Delagoa Bay to free the Transvaal from its dependence upon British trade routes; but not a single track of the railway was laid, whereas the loan strained the meagre resources of the republic and alarmed the Cape and Natal merchants whose interests it threatened. When in 1876 Burgers personally waged an unsuccessful campaign against the Pedi (one of the Sotho peoples) in the northern Transvaal, he was totally discredited. The Afrikaners, including Paul Kruger, were plotting against him, and the traders were conniving with the Cape and Natal merchants to bring in the British. Carnarvon heard their cries and commissioned Shepstone to annex the Transvaal. Entering the republic in January 1877 with 25 police and a staff of seven, Shepstone annexed it in April in a proclamation which promised "the fullest legislative privileges compatible with the circumstances of the country and the intelligence of the people."

But British rule in the Transvaal was neither efficient nor tactful and the elected legislature did not materialize. Then the Zulu War revealed the weakness of British arms: the Zulu, their martial spirit revived by Cetshwayo (*q.v.*), routed a large British force at Isandhlwana in 1879 before they were vanquished in the following year (*see* ZULULAND). By that time the Transvaalers, who had passively acquiesced in the annexation, were moving toward open rebellion under the leadership of Paul Kruger, Petrus Jacobus Joubert (*qq.v.*), and M. W. Pretorius, and in 1881 they, too, wiped out a British force at Majuba. Gladstone's ministry, which assumed office in Britain in 1880 but failed to reform the Transvaal administration in time to avert the rebellion, then gave the Transvaalers a qualified independence (Pretoria Convention, 1881). Three years later they allowed the republic full internal autonomy, while maintaining British control over its relations with foreign states, other than the Free State (London Convention, 1884). Carnarvon's project had completely miscarried, and his permissive act for the unification of South Africa (1877) was stillborn.

3. The Rhodes-Hofmeyr Alliance.—In the Cape, which remained the most civilized of the South African states, the advent of responsible government and the series of British annexations prompted a group of Afrikaners to form a political organization, the Afrikaner Bond, in 1879. At first the Bond's program was crudely sectional, but three years later Jan Hendrik Hofmeyr (*q.v.*) gained control and turned it in the direction of Anglo-Afrikaner cooperation, with a British South African federation, which should include the republics, as the ultimate goal. Meanwhile Cecil Rhodes had entered the Cape Parliament and, as his vision of British expansion in Africa was reconcilable with Hofmeyr's, he was able to form a ministry with Bond support in 1890.

Meanwhile, although it had washed its hands of Basutoland in 1884, the Cape Colony by 1894 had annexed all the land below the mountain escarpment as far east as the Natal border at the Umzimkulu River. The Nguni inhabitants of these Transkeian territories remained in occupation of most of their lands after their political autonomy had been extinguished; but steps were taken to prevent them exercising much influence over the colonial Parliament. Laws were passed providing that land occupied on tribal tenure should not satisfy the economic requirement for the franchise (1887) and raising the economic qualification and introducing a simple educational test (1892). A start was also made in encouraging African communities to adopt individual land tenure and to elect local administrative councils (1894). Thus the Cape government drew a line between "tribal" and "civilized" Africans, treating tribal Africans as minors and giving civilized Africans the same rights as white men in theory, though in practice not many Africans got the vote. By 1895, therefore, the Rhodes-Hofmeyr alliance was bidding fair to heal Anglo-Afrikaner tensions in the Cape Colony, without destroying the prospect of a constructive relationship with Africans.

4. British Clash with the Transvaal.—During the late 19th century the Bantu-speaking tribes of South Africa which had previously maintained their autonomy north of the Vaal River came under white control as a result of Boer expansion and the intervention of Germany and Britain. In 1884 Germany took over South West Africa and Transvaalers began to encroach westward toward it, setting up the republics of Stellaland and Goshen. This expansion, which seemed likely to cut off the British from access to central Africa via the Cape, was checked, largely on the insistence of Rhodes, in 1885, when Great Britain, after a display of force, proclaimed a protectorate over northern Bechuanaland and annexed southern Bechuanaland as a crown colony. Transvaal efforts to keep their north clear of the British were also foiled by Rhodes, who secured a prospecting concession from the Ndebele chief Lobengula in 1888, obtained a royal charter incorporating the British South Africa Company to exploit the concession in 1889, and dispatched a pioneer expedition to occupy what became known as Rhodesia in 1890 (*see* RHODESIA: *History*). Finally, the Transvaalers tried to push toward the east in order to get a port on the Indian Ocean, but, although they incorporated fresh territory, including Swaziland, they did not reach the coast, as Britain annexed Zululand in 1887 and Tongaland, the last gap, in 1895. The Afrikaner republics were thus encircled by the colonies of Great Britain and its oldest ally, Portugal—hemmed in a kraal, as Paul Kruger complained. Southern Bechuanaland was taken in by the Cape Colony in 1895; Zululand and Tongaland by Natal in 1897; but northern Bechuanaland remained a British protectorate.

In 1883 Paul Kruger was elected president of the Transvaal. His character had been molded in the hard school of the Great Trek and of commando fighting against Afrikaner factions and African tribes; and recently he had led the opposition to President Burgers and the British. His policy was to regain complete independence for the republic and to preserve Afrikaner control of it. In 1885 he was constrained to suggest a customs union with the Cape, whose government rejected the offer. Soon afterward his financial difficulties were solved by the gold discoveries and he proceeded to use the mining industry as a milch cow, imposing heavy taxation and granting monopolies of essential materials, such as dynamite.

The growth of such an industry in the heart of his republic, however, posed serious problems. The Afrikaners became outnumbered by the newcomers who poured in from all parts of the world, most of them British subjects. To give these *uitlanders* ("outlanders"), as they were called, an effective vote seemed like

suicide; to withhold such a vote was bound to cause trouble with the British. Kruger and the *Volksraad* never hesitated: they progressively raised the franchise qualifications until by 1894 no *uitlander* could vote in presidential elections, and only those who were 40 years old and had lived 14 years in the Transvaal, during 12 of which they had been subject to an oath of allegiance, could vote in *Volksraad* elections. In short, on the one hand the government got most of its revenue from the *uitlanders* and denied them political rights; on the other hand the *uitlanders* continued to swarm into the republic where many of them prospered exceedingly. Such a situation required patience. Although Kruger was reelected for a third term in 1893, his majority over the more moderate P. J. Joubert was small and a change seemed likely in 1898.

But Rhodes was not patient. Finding that Kruger stood between him and a British South African federation, he planned to overthrow him. Kruger nearly played into Rhodes's hands in 1895 when, contrary to the London Convention, he tried to injure Cape trade with the Transvaal and the Cape railways that were competing with the Delagoa Bay line by making the rates over the Transvaal sector of the Cape line prohibitive and by closing the Vaal drifts to prevent the carriage of goods by wagon. But he gave way when the colonial secretary, Joseph Chamberlain, agreed to support the Cape ministry's protests, by force if necessary.

Rhodes then pushed ahead with his conspiracy: the *uitlanders* were to rise, an armed force under Leander (afterward Sir Leander) Starr Jameson (*q.v.*) was to go to their assistance, and the high commissioner was to hurry to Pretoria to "restore order." Chamberlain knew of Rhodes's plans when he provided a suitable jumping-off place for Jameson's force by ceding to the British South Africa Company a strip of land along the Transvaal border of the Bechuanaland Protectorate, but he later withdrew his support when he learned that the *uitlander* rising would not take place to give the invasion an air of respectability. Therefore, when Jameson, contrary to Rhodes's last-minute instructions, rode into the Transvaal from Pitsani near Mafeking on Dec. 29, 1895, he was disowned by the colonial secretary and the high commissioner. Four days later he surrendered to Transvaal commandos at Doornkop.

5. Outbreak of the South African War.—The raid fiasco cleared the decks for the South African War. Rhodes had to resign the premiership of the Cape Colony, where, in 1898, W. P. Schreiner became head of a ministry which relied upon the support of the Afrikaner Bond, now deeply suspicious of British designs. In the Orange Free State, which had opposed the Transvaal over the drifts crisis, M. T. Steyn was elected president and formed a military alliance with the Transvaal. While Steyn and the Bond were not uncritical of the Kruger regime, Kruger's Anglophobia seemed to have been vindicated in the Transvaal, where he won the 1898 presidential election by a large majority. In England, on the other hand, a parliamentary committee failed to probe Chamberlain's dealings with the raiders, a telegram from the German emperor congratulating Kruger turned Jameson and Rhodes into popular heroes, and the press paid much attention to *uitlander* grievances.

As the tension mounted, Chamberlain, taking the high ground of British paramountcy in South Africa, claimed to be competent not merely to control the foreign relations of the Transvaal (a right expressly granted by the London Convention) but also to intervene on behalf of the *uitlanders* (which was not). If the right to intervene existed, there were grounds enough for exercising it. The tendency of the *Volksraad* to give sweeping powers to the president was exemplified in the judges' crisis: in 1897 Chief Justice John (afterward Sir John) Gilbert Kotze delivered a judgment which meant that the greater part of the laws of the Transvaal had been enacted unconstitutionally and were null and void, whereupon the *Volksraad* deprived the courts of the testing power and gave Kruger the power to dismiss any judge who disagreed; and the next year Kruger dismissed Kotze. In 1898 an Anglo-German agreement removed the likelihood of German intervention in the event of war in South Africa, and Chamberlain and the high commissioner, Sir Alfred (afterward Viscount) Milner, proceeded to apply the screw. In so doing they brushed aside several attempts by the Cape government and the Afrikaner Bond to avert a catastrophe.

The central issue was the Transvaal franchise. In June 1899, in conference at Bloemfontein, Milner proposed a simple five years' franchise, Kruger refused, and the negotiations collapsed. The last chance of peace was lost in August when Jan Christiaan Smuts (*q.v.*), Kruger's young state attorney, offered a five years' franchise and Chamberlain rejected the conditions that were attached to the offer. Milner had long since made up his mind that war was "inevitable," and in September Chamberlain arranged for 10,000 British troops to be sent to augment the meagre British forces in South Africa. The republicans, who had been arming furiously for several years, replied by issuing an ultimatum which expired on Oct. 11, 1899. (For events of the war and for the Treaty of Vereeniging that ended it, *see* SOUTH AFRICAN WAR.)

6. Reconstruction and Union.—After the peace of Vereeniging, Milner, high commissioner and governor of the crown colonies —the Transvaal and the Orange River Colony—concentrated on their material reconstruction from the ravages of war. The gold mines resumed large-scale operations, and the Afrikaners were returned to their land from the prison and concentration camps and supplied with food, stock, seed, and implements, no less than £10,000,000 being spent by Great Britain on their rehabilitation. Milner also prepared the ground for political union by bringing all the colonies into a South African customs union and by amalgamating the railways of the Transvaal and the Orange River Colony.

All this work was well done by Milner and his band of able young men, who were dubbed the "kindergarten." But the opportunity was not used to emancipate the nonwhite inhabitants of the crown colonies from their legal disabilities, which remained much as they had been during the republican regime. Nor did Milner gain the confidence of the Afrikaners: they disliked him as "the man who made the war," who openly supported an agitation for the suspension of the Cape constitution in 1902, who imposed an English educational system on the crown colonies, and who was responsible for bringing Chinese labourers to the Witwatersrand gold mines in 1904. For the importation of Chinese labourers there were, indeed, strong economic reasons, because the supply of African mine labour had temporarily fallen off; but in Britain the

decision played a large part in the fall of A. J. Balfour's Conservative government in December 1905, and the change of government was followed by a radical change in the distribution of power in South Africa.

Sir Henry Campbell-Bannerman's Liberal ministry, anxious to make amends to the Afrikaners for a war which had been brought about by its predecessors, decided to give the new colonies responsible government, with exclusively white electorates. The Liberals defended this decision by referring to the Treaty of Vereeniging, but it did not, in fact, debar them from allowing Coloured and Asian people to vote. Consequently in March 1907 Louis Botha (*q.v.*), former commandant general of the forces of the South African Republic, became premier of the Transvaal, with Smuts as his right-hand man, and in December 1907 A. Fischer became premier of the Orange River Colony. The swing of the pendulum was finally completed in February 1908, when J. X. Merriman's South African Party, consisting largely of members of the Afrikaner Bond, ousted Jameson's Progressives from office in the Cape Colony.

The high commissioner, Lord Selborne, who succeeded Milner in 1905, argued the case for union in a memorandum published in July 1907, and, once in power, the three Afrikaner parties took it up enthusiastically, with the support of their oppositions. White public opinion in South Africa moved steadily in favour of union, partly out of an idealistic feeling that it was best to bury the hatchet and make a new start on a basis of white equality, and partly because an African rebellion in Natal in 1906 led many to think union essential for white security; some, moreover, saw in union the best way of guarding against any further British interference in South African affairs. There were also compelling economic reasons for union: the four colonies were interdependent and yet, without political union, their material interests were so divergent that the customs union seemed almost certain to collapse.

Accordingly a national convention, comprising 30 members appointed by the four colonial parliaments and 3 nonvoting members from Rhodesia, met in 1908 and 1909 under the chairmanship of Sir (afterward Baron) John Henry de Villiers, chief justice of the Cape. A constitution was drafted and unanimously approved by the convention and it was carried with scarcely any dissentients in the parliaments of the Cape Colony, the Transvaal, and the Orange River Colony, and by a three-to-one majority of the electorate in a referendum in Natal. It was enacted by the British Parliament in September 1909, substantially as it had been submitted to the British government by delegates from South Africa. The South Africa Act came into force on May 31, 1910, and the four colonies became the provinces of the Union of South Africa (*see* also *Constitution*, below).

The convention, except for the Natal members, wanted a close union and complete flexibility, and they were largely successful; the principal feature of the South African constitution was the grant of power to Parliament to legislate on practically every subject by simple majorities in each house. Nevertheless, on two subjects they did not grant Parliament such extensive powers. First, the Afrikaner members wanted special protection for the section which gave Dutch (to which Afrikaans was added in 1925) equal status with English as an official language of the Union. Second, the convention could not agree on a uniform franchise for the Union, the Cape delegates favouring a colour-blind franchise and the others a rigid colour bar. Eventually a compromise was reached whereby the franchise qualifications were to remain as they were in each province and the established franchise rights of the Cape nonwhites were specially protected. Accordingly, the sections on language equality and the Cape nonwhite franchise were to be amended only with the approval of two-thirds of the members of both houses of Parliament in a joint sitting. The act also made it possible for Rhodesia to join the Union on terms to be approved by the Privy Council and for the High Commission Territories of Basutoland, the Bechuanaland Protectorate, and Swaziland to join on terms laid down in a schedule, but only with the consent of the imperial government, which had special commitments to their African inhabitants.

D. The Union and the Republic

1. The Race Issue.—The dominating factor in the history of South Africa has been the exceptionally complex character of the population. In 1910 there were nearly 6,000,000 inhabitants, of whom 21.5% were whites, 67% Africans, 9% Coloured people, and 2.5% Asians. By 1960 there were 16,000,000, of whom 19.3% were whites, 68.3% Africans, 9.4% Coloured people, and 3% Asians. In 1910 the whites included an Afrikaner majority, mainly rural, and a British minority, mainly urban. Between them they owned most of the land and the capital, did most of the skilled work, and possessed 93% of the votes.

The Africans were still predominantly tribal rather than modern in culture, but, as a result of their conquest and of white missionary activity and economic enterprise, there was already a distinct trend toward the disintegration of tribalism. Although most Africans still had homes of sorts in the reserves, those were scattered lands which amounted to only one-fourteenth of the area of the country and by no means provided them all with a livelihood; consequently, many Africans went out to earn wages on white farms and in the towns. Moreover about 1,000,000 Africans had long been established as squatters on white farms and a few were already completely urbanized. The Africans were subject to pass laws which restricted their movements outside the reserves, to Masters and Servants laws which made breach of contract a criminal offense in many types of employment, to special taxation, and to other special laws. These laws varied from province to province, and in the Cape about 7,000 African voters were exempted from some of them.

The Coloured people were Western in culture. Most of them lived in the Cape Province, where their legal status was that of the whites, and about 14,000 were voters, whereas in the other provinces they were subject to discrimination.

The Asians were mainly the product of the indentured Indian immigration scheme to Natal, where they outnumbered the whites and were subject to special laws, including a £3 tax. They were excluded from the Orange Free State, but about 11,000 had settled in the Transvaal, where, too, they came under special laws.

The policies of South African governments differed on many important issues; but all, being responsible to a predominantly white electorate, stood more or less explicitly for "the maintenance of white supremacy," a task which became increasingly difficult as a result of the rapid tempo of economic development in South Africa and the change in the balance of power and the climate of public opinion elsewhere.

2. The Botha-Smuts Regime, 1910–24.—In 1911 the Afrikaner parties of the former colonies merged to form the South African Party, which, under Botha and Smuts, governed the country until 1924. Botha and Smuts had been zealous fighters for republican independence so long as there was a chance of success, but they were realistic enough to accept the inevitable at Vereeniging and imaginative enough to see great prospects for South Africa when the hot mood of British imperialism had spent itself. By 1910 they hoped for the coalescing of the British and Afrikaner elements into a white South African nation which would freely cooperate with the British Commonwealth in peace and in war. The ideal went too far, however, for the more conservative Afrikaners, who were concerned with preserving their group identity, and not far enough for the more self-conscious nonwhites, for whom it implied a permanently inferior status.

The government wished to keep most of the Africans in the reserves to prevent the whites from being swamped, and to use African manpower as the unskilled base of all forms of economic enterprise—objectives which involved certain contradictions. As the Africans became more accustomed to a money economy, some of them were liable, unless checked by law, to compete successfully with the less efficient whites. This was already happening in the gold-mining industry, and laws were passed in 1911 to preserve the racial hierarchy in that industry. Such competition was also happening in some rural areas, where Africans were pooling their resources to buy more land; a Natives Land Act was passed in 1913 to limit the areas within which such purchases could be made. Neither of these acts was wholly effective. In 1916 a

commission reported that if the policy of territorial segregation was to be carried out the reserves should be substantially increased in size, but little was done about it because the whites were not prepared to make the necessary sacrifices.

The Asian question had reached a more crucial phase. Already before union Mohandas Gandhi (*q.v.*) had organized nonviolent resistance against the Transvaal government, and after union he resumed the struggle against the £3 tax in Natal. As a result the Indian government stopped the importation of indentured Indian labourers in 1911 and the £3 tax was removed in 1914. By that time the pattern of later disputes had developed: the Union government regarded the Indians as temporary visitors and tried to persuade them to return to India; and most of the Indians regarded themselves as permanent residents and demanded full rights of citizenship.

The conservative Afrikaners had found their leader in J. B. M. Hertzog (*q.v.*). Although he had joined the Botha cabinet in 1910, Hertzog regarded his colleagues' policy as liable to cause the Anglicization of the Afrikaner people, and he publicly advocated a different, "twin-stream" policy, which led to his exclusion from a reconstituted cabinet in 1912 and to the foundation of the Nationalist Party. When in 1914 the government unhesitatingly took the part of Great Britain in World War I and Parliament voted funds for the conquest of German South West Africa, a number of former republican generals, some of whom held appointments in the South African defense force, came out in rebellion to avenge Vereeniging. After mastering the revolt, Botha took command of the South West African expedition and forced the Germans to capitulate on July 9, 1915. South African volunteer contingents also fought in East Africa and on the Western Front in Europe and many individuals joined British units. Smuts, after serving as commander in chief in East Africa, did notable work in the British war cabinet. In July 1919 he and Botha, on behalf of South Africa, signed the Treaty of Versailles and the covenant of the League of Nations, under which South West Africa became a Union mandate. Back in South Africa Botha died before August was out, and Smuts, succeeding to the premiership, faced the discontents caused by thwarted Afrikaner nationalism, a steep rise in the cost of living, and industrial troubles.

As early as 1907 Smuts had intervened on the side of the employers in a strike of white workers on the Witwatersrand, and in 1914 he had ended another strike by declaring martial law and illegally deporting nine strike leaders. After the war there was a serious crisis. In December 1921 the Chamber of Mines, faced with rising costs and a fall in the price of gold, decided to organize the industry more rationally by using Africans for semiskilled work. There was a violent reaction by white labour, which Smuts suppressed at a cost of 230 lives. The result was that, although the threat to relax the colour bar was not carried out, the Labour Party, representing the aggrieved white workers, made an electoral pact with the Nationalists. In the hope of redressing the political balance Smuts wooed the Southern Rhodesian electorate to accept incorporation in the Union, but when a referendum was held on the issue in 1922 they preferred to remain separate. Two years later the South African Party was heavily defeated at the polls and Hertzog became premier of a Nationalist-Labour coalition.

3. Hertzog's Nationalist Policy, 1924–33.—Hertzog's main objectives were to complete the emancipation of South Africa from imperial control and to provide greater protection for the whites from the Africans and for the Afrikaners from the British. He played a notable part in the events leading to the Balfour Report (1926) and the Statute of Westminster (1931), which gave statutory definition to the established convention that the British government could not exert authority over a dominion. South Africa's sovereign status was also asserted by the adoption, after a long and bitter controversy, of a distinctive national flag (1927), by the appointment of ambassadors to Italy, the United States, and the Netherlands (1929), and by the separation of the office of governor-general, the head of the South African government, from that of high commissioner, the representative of the British government in South Africa (1931).

Economic nationalism was fostered by the foundation of a state-controlled iron and steel works at Pretoria, by increased protection for agriculture and industry, by a reduction in imperial preferences, and by a commercial treaty with Germany. White supremacy was bolstered by the provision of sheltered employment for "poor whites" in state enterprises; by a Mines and Works Amendment Act (1926), which was more effective than its predecessor in shutting Africans out from skilled mining trades; by a Native Administration Act (1927) and a Riotous Assemblies Act (1930), which gave the executive wide powers over individuals; and by franchise acts (1930–31), which extended the vote to all white men and women, while they left the Cape nonwhite vote as before, restricted to men who possessed property and educational qualifications. Hertzog's legislative program was still incomplete when the world depression undermined the prosperity of the country and the popularity of the government, which continued to cling to the gold standard after Great Britain had abandoned it in 1931. After the government, yielding to pressure from some of its own supporters, left the gold standard in December 1932, there was a fairly rapid economic recovery, but political confusion continued until, in 1933, Hertzog and Smuts formed a coalition government which secured overwhelming support from the electorate.

4. Hertzog-Smuts Regime, 1933–39.—The coalition was based on a great deal of common ground between Hertzog and Smuts. Hertzog no longer feared political cooperation with Smuts's British supporters, believing that the Afrikaners had been raised to the point where they were immune from the danger of Anglicization, and Smuts was reconciled to most of Hertzog's achievements and was prepared to collaborate with him in rounding them off. Consequently, in 1934 the two major parties fused to form the United Party; but Hertzog failed to carry with him a small group of Afrikaner irreconcilables, led by D. F. Malan (*q.v.*), who formed the Purified Nationalist Party, while C. F. Stallard at the other extreme dissociated himself from Smuts and formed the Dominion Party. By then the constitutional settlement had been completed by the Status Act and the Seals Act (1934) which secured, so far as words could do, that South Africa was master in its own house. The government then proceeded to complete Hertzog's segregation legislation. A Representation of Natives Act (1936) removed the Cape Province African voters from the common roll and gave them the right to elect three white members to represent them in the lower house, gave the Africans throughout the Union the right to elect four white senators, and created a Natives' Representative Council with advisory powers. A Native Trust and Land Act (1936) provided for a considerable increase in the size of the reserves. A Native Laws Amendment Act (1937) authorized the executive to prevent more Africans from entering the towns and to compel municipalities to segregate African from white residents. It was Hertzog's hope that the enlarged reserves would become capable of maintaining almost all the African people, so that those who worked for whites could be regarded as temporary visitors from the reserves. But it is notable that he saw the need for consultation with an African council, and that he did not try to discriminate against the Coloured people. Moreover, his government expanded the social services not only for the whites but also for the nonwhites; there was, for example, a considerable increase in government grants for education.

Nevertheless, Africans, Asians, and Coloured people were becoming disturbed by the great contrast between their living standards and those of the whites and by an accumulation of laws which caused 500,000 Africans to be convicted of statutory and municipal offenses in a year and many more to come into unpleasant contact with a police force recruited from among the poorer Afrikaners, who were imbued with the strongest race prejudices. As tension began to mount the Nationalists claimed that "white South Africa" would not be safe unless the restrictions on Africans were increased and the Coloured people were also segregated from the whites. Though Hertzog strongly disagreed, the Nationalists were able to profit from the celebrations held to mark the centenary of the Great Trek in 1938, when they appealed to all Afrikaners to remain true to the principles of the *voortrekkers* and of Paul Kruger, placing special emphasis on their race attitudes.

5. World War II.—The outbreak of World War II caused a

crisis in South Africa. Although Hertzog and Smuts had cooperated successfully on many issues, they differed widely on foreign affairs. Hertzog took an indulgent view of Nazi Germany, believed that its expansion was no concern of South Africa, and moved in the House of Assembly, on Sept. 4, 1939, that South Africa should remain neutral. Smuts, keenly aware of the wider implications of Naziism, maintained that it was the interest and the duty of South Africa to support Great Britain, and he won the crucial division by 80 votes to 67. On Sept. 5 Smuts formed a ministry with the support of the Labour Party, the Dominion Party, and the majority of the United Party, and war was declared on Germany.

The Smuts government concentrated its energies on the war. About 200,000 white men (more than half of them Afrikaners) and 125,000 nonwhites (mainly Africans and Coloured men) joined the forces, and many of them served with distinction in the Ethiopian, Mediterranean, and Madagascan theatres of war. The nonwhites were not allowed to bear arms but were distributed among the combatant units, for whom they performed vital work as stretcher-bearers, labourers, etc. Industry was efficiently switched to the production of munitions and clothing for military purposes. Smuts himself remained in close contact with Winston Churchill and watched carefully the strategy of the war, often leaving his able lieutenant, J.H. Hofmeyr, Jr. (1894–1948), to carry a lion's share of the burden of administration.

South Africa's achievements were impressive, considering the strength of the opposition to the war. Fortunately for the government, the opposition splintered into fragments during the most critical period: J. F. van Rensburg's Ossewabrandwag ("Guard of the Ox Wagon") and Oswald Pirow's New Order, accepting the racial doctrines of the Nazis and their contempt for parliamentary government, patently hoped to profit from a Nazi victory; the Malanites expounded the ideal of an Afrikaner republic in which, as in Kruger's republic, the British would not necessarily have political rights; while the Hertzogites stood firm by their principle of equality between the whites. In the first flush of his disappointment, indeed, Hertzog led his defeated minority from the United Party to join hands with Malan and form the Reunited Nationalist Party, but the reunion was not a happy one and before the end of 1940 Hertzog had been driven out for his tenderness toward the British. His colleague, N. C. Havenga, subsequently founded the Afrikaner Party to maintain his ideals.

The general election of 1943 was a victory for Smuts in that his prowar coalition secured a majority of 67 seats in a lower house of 153; but it was also in a sense a victory for Malan's Nationalists, who won all the 43 opposition seats. Thereafter, as the prospect of a Nazi victory faded, the Nationalists consolidated their position as the political instrument of self-conscious Afrikanerdom, absorbing elements from the Ossewabrandwag, the New Order, and the Afrikaner Party, and drawing support from a variety of cultural and economic organizations, including the Broederbond, a secret group of Afrikaner elite.

As the war drew to a close Smuts drafted the preamble to the United Nations Charter signed at San Francisco in 1945 and returned to mold postwar South Africa along the lines of a generous demobilization scheme, an expansion in the social services for all races, a planned development of agricultural, mineral, and industrial resources, and large-scale white immigration.

6. Industrial Expansion in South Africa.—Subsequent events can be understood only in relation to the fact that from about 1938 onward South Africa was experiencing an industrial expansion as intense as the British industrial revolution of the early 19th century, with the added complication of racial differences between the unskilled workers on the one hand and the skilled workers, the capitalists, and the majority of the electorate on the other. The way had already been paved by the rise of the mining industries and by the foundation of many manufacturing industries during World War I and the 1930s; the rate of expansion increased during and after World War II. In the 24 years between 1936 and 1960 the total population increased by 67%. In the 28 years between 1935 and 1963 the geographical national income at current prices increased more than eightfold (the value of mining production fivefold, of agricultural production sixfold, and of manufactures thirteenfold). In the same period the price index increased by two-and-a-half times; so that even allowing for the change in the value of money, the growth of manufacturing industries was remarkable.

The gold-mining industry continued to play an important role in the South African economy, especially in easing the balance of payments problem. Fears that the supply of gold would soon be exhausted were removed by the opening up of new mines on the Far West Rand and in the Orange Free State, where production started in 1951. Nevertheless, gold production did not increase as rapidly as other industries and the relative importance of goldmining decreased as the economy became more diversified. The mining industries continued to be organized on racial lines and the manufacturing industries adopted a similar basis. Skilled work in South Africa remained virtually a white monopoly and was well paid; most of the unskilled work continued to be performed by nonwhites for low wages.

As a result of this expansion more than four-fifths of the white population were townsmen by 1960, the "poor whites" were absorbed by industry, and the earlier economic distinctions between the Afrikaners and the British inhabitants became blurred. Industry also attracted many nonwhites. More than 3,500,000 Africans (nearly a third of the total African population) were in the towns at the time of the 1960 census. Into some of these towns the influx was so rapid that housing and other amenities were grossly inadequate and there was much crime. But in spite of low wages and squalid living conditions, the urban Africans earned far higher incomes than the rural Africans did.

7. The 1948 Election.—As the 1948 election approached, disturbing facts were becoming known in South Africa. Although the reserves had been enlarged under the 1936 act, only 40% of the African population was to be found in them at the time of the 1946 census. The Social and Economic Planning Council reported that the quality of the reserve lands was deteriorating; and early in 1948 a commission revealed that many Africans were becoming permanent inhabitants of the towns. These facts did not square with the argument that the Africans had adequate homes in the reserves and could therefore be treated as inferiors elsewhere. Moreover the Natives' Representative Council was frustrated because the government ignored its advice and the African National Congress, which had been cautious since its foundation in 1912, was now demanding the removal of discriminatory laws in terms of the ideals of the United Nations. This raised the question whether white supremacy, which had developed in the simple pastoral economy of the 18th century, could be maintained in the industrial economy of the 20th century.

The Smuts government continued to profess adherence to the segregation policy but tried to deal with practical grievances in a conciliatory spirit, while Hofmeyr went farther than his colleagues on occasion, feeling toward a policy which might be acceptable to all races. But Asians were protesting vigorously against legislation that prevented their buying or occupying new premises in Durban, and the Indian government attacked South Africa in the United Nations General Assembly. Consequently, when Smuts tried to persuade the assembly in 1946 to allow the Union to incorporate South West Africa, he met with a rebuff, and the assembly passed the first of a series of resolutions condemning racial discrimination in South Africa.

The Nationalist leaders wished to reduce South Africa's links with Britain, the Commonwealth, and the United Nations, to advance the power of the Afrikaner people, and, above all, to preserve white supremacy by every possible means. They expressed horror at the "liberalism" of the United Party, declared it would cause the "suicide" of white South Africa, and proclaimed a policy of apartheid (*q.v.*), according to which whites, Coloureds, Asians, and Africans would be separated from each other and each race would be able to "develop along its own lines in its own area." Though as far as the Africans were concerned this was little more than Hertzog's segregation policy in a new dress, it was presented to the electorate as something new and dynamic. The Nationalists also exploited the discontents caused by wartime controls and were

assisted by the fact that the electoral system favoured the rural voters. The result was that in May 1948 Malan, with the assistance of Havenga's small Afrikaner Party, was able to form a government, with a majority of five in the House of Assembly. This result, which was a surprise to Malan as well as to Smuts, was decisive for South Africa.

8. Nationalist Party Policy from 1948.—After the 1948 election the Nationalist Party consolidated its power, absorbing the Afrikaner Party and gaining strength in the House of Assembly in each election—from 73 seats in 1948, to 94 in 1953, to 103 in 1958, to 105 in 1961, and to 126 (in a larger House) in 1966. The process was promoted by legislation and administrative action: Smuts's immigration scheme was scrapped; British immigrants, like others, were required to wait several years before they could vote; the white people of South West Africa were given six seats in the House of Assembly; the voting age was lowered to 18; and the Coloured voters were given separate and limited parliamentary representation and the representatives of the Africans were removed from Parliament. Nationalist power was also promoted by the strong leadership of the prime ministers Malan (1948–54), J. G. Strijdom (*q.v.;* 1954–58), and H. F. Verwoerd (*q.v.;* 1958–66). The United Party, led by J. G. Strauss after the death of Smuts in 1950 and by Sir D. P. de Villiers Graaff from 1956, remained the main opposition party, but it lost seats at each election and suffered from secessions on both flanks. Several new parties were founded, including a Liberal Party and a Progressive Party, but they had little success at the polls.

The Nationalist governments enacted a mass of racial legislation to preserve white supremacy. They created a population register to fix the racial category of every South African. They made marriages and unions out of wedlock between whites and nonwhites unlawful. They systematically divided the towns as well as the rural areas into zones in which members of only one race could own or occupy property or conduct business. They assumed control over African and Coloured school education, eliminating the mission schools. They excluded nonwhites from the established universities and founded separate colleges—one each for Coloureds, for Asians, for Xhosa, for Zulu, and for Sotho. They intervened in the labour-union movement to separate white from nonwhite. They gave officials sweeping powers to remove "undesirable" Africans from towns. They extended the practice of reserving particular types of jobs for whites. They enforced segregation where it did not previously apply, as in buses, trains, post offices, libraries, motion-picture houses, and theatres in the Cape Peninsula. White and nonwhite South Africans could thus rarely meet, except as masters and servants or rulers and subjects.

Nonwhites were almost totally excluded from the authoritative political system. After a long struggle the Cape Coloured voters were removed from the common voters' roll and given the right to elect four whites to represent them in the House of Assembly. At first the government lacked the two-thirds majority laid down in the South Africa Act for such legislation. An act removing the Cape Coloured voters from the common roll was passed through Parliament by the ordinary simple-majority procedure in 1951, to be declared invalid by the Supreme Court. Under a further act the Nationalist members of Parliament then sat as a high court and reversed the judgment, but the Supreme Court held that the "high court of Parliament" was itself invalid. Eventually the Senate was enlarged and its composition changed to give the Nationalists 77 seats out of 89 in that house (1955). The Coloured voters were then removed from the common roll by the necessary two-thirds majority in a joint sitting of both houses, and the Supreme Court acquiesced (1956).

In 1959 the representatives of the Africans were removed from both houses of Parliament and the Cape Provincial Council. The House of Assembly then contained 156 whites elected by the white voters of the Union, later Republic, and South West Africa and four whites elected by the Cape Coloured voters. In 1966 the House of Assembly was enlarged to 166. The Senate, as again reconstituted in 1960, contained 43 whites elected by white electoral colleges and 11 nominated by the government. All provincial councillors were white people elected by white voters, except two in Cape Province who were elected by Coloureds. Thus the compromise embodied in Hertzog's 1936 legislation was destroyed. The only nonwhites who had any say in the composition of the Parliament, which was supreme over all South Africa, and in the principal subordinate bodies, the Provincial Councils, were the Coloured people of Cape Province, and their say was meagre.

Instead, the nonwhite peoples were given various types of segregated subordinate institutions. For the Africans there was a system of "Bantu authorities" in the Bantu areas, consisting mainly of chiefs, councillors, and their nominees. The chiefs were on the government's payroll and were dismissible by the government. In the Transkei, the largest Bantu area, a Legislative Assembly, with a majority of chiefs ex officio and a minority of members directly elected by Africans, and a cabinet and prime minister responsible to the assembly, were established in 1963. Such bodies had powers in defined fields, but subject to the overriding authority of the government of South Africa. The first prime minister of the Transkei was Chief Kaiser Matanzima, who had the support of the chiefs in the assembly but not of the elected members, and who endorsed the principle of racial separation. In the towns some Africans could elect members of Bantu urban councils. A Coloured Persons Representative Council with an elected majority was established in 1964; and a similar body was envisaged for Asians. The Bantu urban councils and the Coloured Persons Representative Council had no more than advisory powers.

The other major achievement of the Nationalists was to change South Africa into a republic. In a referendum in 1960 a small majority of the white voters expressed a preference for a republic. In March 1961 Verwoerd asked a Commonwealth prime ministers' conference whether South Africa might remain a member of the Commonwealth when the change took place; but he withdrew his request when other members of the conference criticized his government's racial policies. Consequently when South Africa became a republic on May 31, 1961, it left the Commonwealth. The republican constitution was substantially the same as the constitution of the Union, except that an indirectly elected state president replaced the queen, and her representative, the governor-general, as head of state. C. R. Swart was elected state president.

9. Internal Opposition to Nationalist Rule.—In spite of all the separatist laws the peoples of South Africa were becoming more and more interdependent as a result of the continuous growth of the modern sector of the economy; and many South Africans, white as well as nonwhite, opposed the government's racial policies. White people of British descent resented the near-monopoly of senior posts in the civil service by Afrikaners, the introduction of the republic, and secession from the Commonwealth. Businessmen, experiencing a shortage of skilled labour, concluded that the colour bar was an impediment to sustained economic growth. Clergy regarded the government's policies as un-Christian and intellectuals regarded them as irrational. Several groups, including the Black Sash, a women's organization, were formed to protest against the most blatant abuses. However, these white critics did not shake the confidence of the government, for the election results showed that it was continuously increasing its electoral support.

African opposition was more serious. The leaders of the ANC organized a series of campaigns to elicit the support of the African masses and to intimidate the government into making concessions; and they had the cooperation of Coloured and Asian congresses and small white groups. In 1952–53 several thousand people, mainly Africans, deliberately courted arrest by "passive resistance to unjust laws." In 1955, 3,000 delegates attended a "Congress of the People" and adopted a "Freedom Charter." In 1957, 45,000 Africans walked many miles from their locations to their places of work in Johannesburg and Pretoria for ten weeks, rather than pay increased bus fares. There were also intermittent riots and clashes with the police in many parts of the country. These reached a high point in 1960. The Pan-Africanist Congress, a radical offshoot of the ANC, organized demonstrations against the pass laws; at Sharpeville, near Johannesburg, the police opened fire against demonstrators, killing 69 Africans and wounding 178; and blood was also shed in Cape Town and elsewhere. Between 1959 and 1961 there was a revolt against the Bantu authorities

system in the Transkei; and between 1961 and 1964 there were several hundred acts of sabotage, in the form of time-bomb attacks upon public buildings and railway and electrical installations in the main industrial centres.

The government responded in an uncompromising manner. Parliament enacted many laws to help the executive break the revolutionary opposition. The nonviolent resistance campaign of 1952–53 was called off in the face of harsh new penalties for protest actions. The Congress of the People movement of 1955–56 collapsed when the government arrested 156 persons and charged them with high treason. Order was restored in 1960 by the declaration of a state of emergency and resort to government by proclamation, and by the outlawing of the ANC and the PAC. The Transkei revolt was handled under proclamations giving extraordinary powers to chiefs and white officials. The sabotage movement of 1961–64 was countered by General Law Amendment acts, which allowed the executive to outlaw any organization, to ban any person from attending meetings or publishing statements, and to arrest any person and hold him incommunicado without trial. The result was that by the end of 1964 all known revolutionary leaders were in prison or exile, all known revolutionary organizations had been broken up, and the radical internal opposition seemed to have been crushed.

10. External Opposition.—There was strong foreign opposition to South Africa's racial policies. The governments of the newly independent African states wished to complete their revolution by destroying the last strongholds of white supremacy in Africa; but although they had the diplomatic support of the Asian and Communist countries, they could not muster enough resources to coerce South Africa without the cooperation of South Africa's principal trading partners—Britain, Western Europe, and the United States. They therefore tried to use the United Nations as an instrument of coercion. The General Assembly had condemned South Africa's racial policies since 1948; the Security Council since 1960. In 1962 the assembly, by majority vote, called on member states to apply economic sanctions against South Africa and to break off diplomatic relations; and in 1964 the Security Council set up an expert committee to consider the feasibility of sanctions. But although Britain, France, and the United States subscribed to many resolutions criticizing apartheid, they did not commit themselves to coercion. In the mid-1960s, when the UN was weakened by its financial problems and the major powers were distracted by the conflict in Vietnam, the prospect of a UN blockade of South Africa seemed to be diminishing. By then, moreover, South Africa had well-equipped and well-trained military forces, consisting of about 125,000 white men, who could be rapidly mobilized and who were capable of overcoming any but a very large-scale attack on South Africa.

Nevertheless, there were still doubts about the future of the regime. Though the radical internal opposition had been crushed, the conditions which had created it continued; and the situations in contiguous territories were fluid. During 1966 Lesotho (Basutoland) and Botswana (Bechuanaland) became independent; Rhodesia's future remained uncertain; Portugal's hold on Angola and Mozambique was being challenged; and, although in July 1966 the International Court of Justice rejected an application brought by Ethiopia and Liberia in regard to South West Africa, in October the UN General Assembly voted to revoke South Africa's mandate over that territory (*see* SOUTH WEST AFRICA: *History*).

Verwoerd, the prime minister, was assassinated in September 1966 and was succeeded by B. J. Vorster, a member of the extreme right wing of the Nationalist Party. (L. M. T.; X.)

V. POPULATION

At the first census (1911) after union the population totaled 5,972,757; by 1960 it had nearly trebled, reaching 16,002,797. The increase is due only slightly to immigration and overwhelmingly to natural increase, which in 1960 was 16.4 per 1,000 for whites, 28.5 for Asians, and 32.9 for Coloureds. No reliable statistics are available for the Bantu (a term that has officially replaced "native" or "African").

From Tables I and II the numerical preponderance of the Bantu in the population is evident. Since 1911 they have maintained their rather more than three to one lead over the whites. About 32% of the Bantu population is urban, the majority living in municipal townships with a considerably smaller number in white areas as servants. Industrial compounds house about 146,000 and about 474,000 live in mine compounds. Of the Bantu rural population (68% of their total numbers) more than half live in the Bantu homelands; most of the remainder are labourers or servants on white farms. Table II shows that the Bantu are most numerous in Transvaal, which is partly because of their extensive employment in the industries of the southern Transvaal industrial and mining area and partly because of the numerous homelands in the

Total	471,445	16,002,797	3,088,492	10,927,922	477,125	1,509,258	33.9

*Data exclude Walvis Bay (374 sq.mi. [969 sq.km.]).

province. The second highest number is in Cape Province because of the population of about 1,500,000 in the homelands of the Transkei and Ciskei. Of the total number in Natal (including Zululand) about 900,000 are in the homelands, the rest being in the white area.

The white population has increased by more than 1,000,000 since 1936. From Table I it is clear that this section of the population is predominantly urban. From Table III it is seen that the majority of urban whites is concentrated in the southern Transvaal industrial area, which includes the Witwatersrand (chiefly Johannesburg, Germiston, Benoni, and Springs), Pretoria, Vereeniging, and Vanderbijlpark. The four ports of Cape Town, Durban, Port Elizabeth, and East London together contain about 646,000 whites. With the provincial administrative capitals Bloemfontein and Pietermaritzburg the white population in these "conurbations" is rather more than three-fifths of the total white population. Of the rural white population about 400,000 are on the 106,000 white farms, which cover an area of about 226,000,000 ac. (91,500,000 ha.).

TABLE III.—*Population, Metropolitan Areas, 1960*

The Coloured population, deriving from a mixture of various racial groups, is concentrated mainly in Cape Province, where it supplies most of the labour for the farming and manufacturing industries. Included for statistical purposes in the Coloured total are 63,000 Malays, of whom 55,000 are urban in Cape Province.

The Asians have increased more rapidly than any other racial group. They consist almost entirely of Indians who were brought over from India in the second half of the 19th century for the Natal sugar plantations. Of the total 477,125 in 1960, 394,854 were in Natal, about 307,000 being urban, and of the urban Asian population 236,477 were in the Durban metropolitan area, exceeding the whites in this area by more than 40,000. (J. H. WN.)

VI. ADMINISTRATION AND SOCIAL CONDITIONS

1. Constitution.—Following the passage of the South Africa Act, 1909, by the British Parliament, the Union of South Africa was formed on May 31, 1910, out of the colonies of the Cape of Good Hope, Natal, Orange River Colony (Orange Free State), and Transvaal, which became the subordinate provinces of the new state. The Union was a member of the British Empire, and its sovereign independence was later guaranteed by the Statute of Westminster (1931) and the Status of the Union Act, 1934. On May 31, 1961, after a popular referendum held among white voters in October 1960, which favoured by a narrow margin the establishment of a republic, the Union became the Republic of South Africa under a constitution adopted by the Union Parliament. On becoming a republic South Africa ceased to be a member of the Commonwealth of Nations (see *History: Nationalist Party Policy from 1948*, above).

The new constitution (further amended in later years) is virtually the same as that of the Union enacted in 1910, with certain changes such as effected in the article dealing with the office of president and substitution of "the State" for "Crown" or "the King or Queen." It provides for a state president (who is head of the republic), an Executive Council of ministers of state appointed by him, a Parliament comprising a Senate and a House of Assembly, and, in each province, an administrator appointed by the state president-in-council for five years, an Executive Committee of four members under the administrator's presidency, and an elected Provincial Council which elects the Executive Committee and, like it, serves for five years. In 1920 the former German territory of South West Africa was assigned to South Africa under mandate. The people of this territory are regarded as South African subjects and are represented in the Parliament of the republic.

The Executive.—The state president is elected for a term of seven years by secret ballot of an electoral college consisting of members of both houses of Parliament. He is a constitutional ruler acting on the advice of his ministers, whom he appoints from among sitting and prospective members of Parliament having the confidence of the majority in the House of Assembly, and they together form a cabinet which in practice is the Executive Council. Ministers in charge of departments may not exceed 18 in number, but the state president may also appoint not more than six deputy ministers.

The Legislature.—Parliament has unrestricted legislative power "to make laws for the peace, order, and good government of the republic." It consists of an upper house, the Senate, and a lower house, the House of Assembly. Ordinarily, it legislates by means of bare majorities in both houses sitting separately, but in the case of the entrenched clause of the Republic of South Africa Constitution Act providing for the equality between the two official languages, English and Afrikaans, it must legislate by means of a two-thirds majority of all members of both houses sitting together.

Although both houses are original legislative bodies, in practice the Senate is in the main a revising chamber with delaying powers in respect of bills introduced in the lower house. In 1960 the Senate's constitution was changed to form a chamber consisting of 54 members, of whom 14 were elected in the Transvaal, 11 in Cape Province, 8 each in Natal and the Orange Free State, and 2 in South West Africa. In addition, eight were nominated for South Africa (four of them for their knowledge of the Coloured peoples) and two for South West Africa, one for similar knowledge. The Coloured population in the Cape had one representative. Qualifications for senators were the same as for members of the lower house, except for a minimum age limit of 30 years. Four seats formerly held by senators elected by Bantu voters were abolished in 1960.

In 1966 the House of Assembly comprised 160 members directly elected by white voters in the republic, 6 members directly elected by white voters in South West Africa, and 4 white members elected by Coloured voters in Cape Province. Three representatives previously elected by Bantu in the Cape ceased to be members of the house in 1960. Members must be adult South African citizens of white descent, and the representatives of white voters are elected from single-member constituencies delimited by a judicial commission at intervals from five to ten years. Seats are allotted to the provinces (and Provincial Councils) in proportion to their adult white population. Under the 1965 delimitation the Cape returned 54 members, Natal 18, the Orange Free State 15, and the Transvaal 73. Electoral divisions within each province have an approximately equal number of voters but may exceed or fall short of the average by between 15% and 30% under a so-called loading system.

With the abolition of Bantu representation and the lowering of the age qualification for white voters in 1959, the parliamentary electorate comprises white South African citizens of both sexes who are 18 years and over and a separate roll of Coloured males in the Cape possessing prescribed literacy and property qualifications.

2. Government.—There are 40 departments of state, staffed by about 260,000 public or civil servants. Departmental responsibility is vested in individual members of the Cabinet, which is presided over by the prime minister. Statutory bodies have been created to supervise broadcasting, electricity supply, and the development of residential group areas according to race; to produce iron, steel, phosphates, and other fertilizers; to extract oil from coal; to finance the development of industries and fisheries; to prospect for petroleum; to develop the Orange River Basin; and to promote the economic development of the Bantu and Coloured peoples in separate areas. The railways, harbours, and air-

ways are operated by an administration responsible to the minister of transport. More than 80 major public bodies have been set up for regulatory and advisory purposes, including an economic advisory council, a national education advisory council, a hotels board, a tourist corporation, and an immigration council.

Provincial Administration.—The legislative powers of the Provincial Councils are defined and limited by the Republic of South Africa Constitution Act of 1963 and by the Financial Relations Consolidation and Amendment Act, 1945, and their ordinances may not be repugnant to an act of Parliament. The constitution guarantees the provincial boundaries. The provincial administrations comprise the administrator; the Executive Committee, which under an act of 1962 is elected by the majority parties in the councils instead of by proportional representation as in the past; a provincial secretary; and various departments and branches. They deal with education, hospitals, roads, shop hours, public entertainments, horse racing, libraries, new townships, town planning, and motor vehicle licensing. They also control local government authorities. Under the constitution, Parliament may not abolish a Provincial Council or abridge its powers except on a petition by the council. The South West Africa administration is similarly constituted with a Legislative Assembly instead of a Provincial Council.

Local Government.—Each province has its own system of local government. In the Cape there are municipalities with city and town councils, village management boards, periurban (suburban) local boards, and divisional councils (rural). They are wholly elected except for local boards. In Natal there are elected city and town councils and town boards, and elected or appointed health committees. Periurban development is controlled by a local health commission appointed by the administrator. In the Orange Free State there are municipalities with city and town councils and village management boards, all elected. Elected small holdings committees of management in periurban fringes or settlements are controlled by an appointed small holdings area control board. In the Transvaal, there are elected city and town councils and village councils, and elected and appointed health committees. Periurban development is controlled by a special health board appointed by the administrator. South West Africa has institutions similar to those of the Cape.

Nonwhite Administration.—Local authorities control Bantu populations within their borders and establish elected Bantu advisory boards in their Bantu townships. In 1961 provision was made for the establishment of partially elected Bantu urban councils in the townships. In the homelands, a reorganization of local government was undertaken into tribal, regional, and territorial authorities under tribal chiefs and the supervision of the Department of Bantu Administration and Development. In 1963 the first Legislative Assembly of 109 members, with a chief minister and cabinet and limited powers (*i.e.*, excluding foreign affairs, defense, etc.) was established in the Transkei homeland, the first of the projected "Bantustans." Local councils for Coloured people are being created in the Cape under the supervision of the Department of Coloured Affairs and the Coloured Advisory Council. A National Advisory Council was set up for the Indian population by the Department of Indian Affairs.

Political Parties.—There are two main political parties in South Africa and one other with representatives in Parliament. They are the Nationalist Party (106 seats in the House of Assembly in 1965), the United Party (49 seats), and the Progressive Party (1 seat). Smaller groups unrepresented in Parliament include the Liberal Party and the Republican Party; Coloured voters are represented by four white members (1 United Party and 3 Independents). The Nationalist Party came into office in May 1948.

3. Taxation.—Three-quarters of national taxation comprises income tax, customs and excise duties, and death duties. There is a growing reliance on the income tax (and supertax) levied progressively, which accounts for more than 50% of total revenue, but incidence is not excessive and is reduced by family and sickness allowances. In 1963 the pay-as-you-earn system of income taxation was introduced. From time to time special repayable tax levies are imposed. The provinces rely mainly on personal and income taxes (18% of their income), motor vehicle licence revenue, and racing and entertainment taxation; but they are state aided to the extent of at least 50% of their income. In 1957 the subsidy basis was revised. Local authorities receive only 7% in grants, and 20% of their income derives from rates on property, generally considered regressive in incidence. Charges for goods and services account for more than 30% and trading profits for more than 10%.

While such taxation facilitates central budgetary control in the interests of economic stability, increasing urbanization throws a growing financial burden on local authorities, and an inquiry into the redistribution of revenue resources began in 1956. By the 1960s approximately 80% of all taxation was levied centrally, 13% provincially, and 7% locally.

4. Living Conditions.—The standard of living is high for the white population; for most Bantu it remains low but is nevertheless higher than in most African countries.

Employment and Wages.—A maximum 46-hour week was introduced in 1941 and the tendency has been to reduce working hours, in some cases to a 40-hour or five-day week. The Industrial Conciliation Act, 1956, provides for the registration of employers' organizations and labour unions, the voluntary settlement of disputes by industrial councils or conciliation boards and, finally, arbitration (which is compulsory in essential services where strikes and lockouts are prohibited). Bantu are excluded from this act and cannot become members of registered unions, but the Native Labour (Settlement of Disputes) Act, 1953, created a central native labour board and subordinate regional committees and labour officers. It also prohibited strikes by, and lockouts of, Bantu. Outside this legislation, wage determinations are made by a wage board established under the Wage Act, 1937, which also determines Bantu wages where the minister refers disputes to it from the Central Bantu Labour Board.

Other legislation includes the Registration for Employment Act, 1945, which created a national employment service (including employment exchanges and extending to sheltered employment and unemployment relief), and the Workmen's Compensation and Unemployment Insurance Acts, 1941. Bantu labour bureaus and unemployment are dealt with by the Department of Bantu Administration and Development, either regionally or through local authorities.

Labour Unions.—Only a few trade unions, properly so-called, survive; *i.e.*, unions that represent the workers in a specific trade. Most unions have become industrial labour organizations, representing all workers in a particular industry. Under the Industrial Conciliation Acts, as amended in 1956, unions are prohibited from affiliation with political parties. In the 1960s the total number of industrial organizations and trade unions exceeded 170, over half of which were for white workers, less than one-quarter were Coloured, and more than one-quarter were racially mixed. The major organizations include the South African Trade Union Council, the South African Federation of Trade Unions, the Koordinerende Raad van Suid-Afrikaanse Vakverenigings, the South African Congress of Trade Unions, the National Union of Liquor and Catering Trades, and the Mechanics Unions' Joint Executives.

Bantu unions do not exist. The rights of Bantu workers are defined by the Native Labour (Settlement of Disputes) Act of 1953. This act provides for a Central Bantu Labour Board, Bantu labour committees and works committees, and Bantu labour officers. Disputes which cannot be settled by the labour officers in collaboration with the regional labour committees and the divisional inspector of labour are referred to the central board. Under the Industrial Conciliation Act (1956) certain occupations are reserved for certain racial groups in order to protect the racial groups from unfair competition.

Housing.—At the 1951 census 564,277 non-Bantu residential units were enumerated, of which 443,616 were occupied by whites. In 1964 new dwellings completed in 18 principal municipalities and 45 smaller towns averaged more than 9,200 a month. Residences for whites are usually built privately, but public housing projects were stimulated by wartime measures that set up a national housing and planning commission with the power to erect houses, to assist local authorities and utility companies, and to make loans to individuals. Most projects are economic or "no-

loss," but assisted housing is provided for lower income groups in which the central and local authorities share the loss. A Ministry of Community Development and Housing was established in 1961 to advance housing programs for all races.

Bantu housing is assisted by a Bantu Housing Board and undertaken in Bantu townships by urban local authorities with public and private funds. A massive project to rehouse urban Bantu was undertaken from 1951 onward. The "squatters' camps," or slum shacks, which had accumulated around towns to which Bantu had been attracted by industrialization, were removed and new townships built. During ten years more than R 200,000,000 (£100,000,000 or $280,000,000) was spent in providing these families with new houses, services, and transport. The townships are planned on modern lines and built by modern methods; each house has its own garden, and there are community amenities, schools, halls, playgrounds, churches, etc. Ethnic groups are housed in their own separate quarters. An example is Daveyton, outside Benoni. Houses are leased, and rents are government-subsidized where incomes fall below R 360 (£180 [$504]) a year (or R 300 in some cases). Bantu have no freehold property rights in townships but may occupy their houses on a long lease. The cost of services to urban Bantu townships is defrayed from funds accruing under the Native Services Levy Act, 1952, which obliges employers to pay a maximum of *2s.9d.* (39 cents) a week for each Bantu employed, part of which is reserved for transport to the townships. Outside these areas Bantu (and also Coloured and Asian) housing is provided by the Group Areas Development Board. Very little nonwhite housing is privately built.

5. Welfare Services.—Welfare services are run by central, provincial, and local authorities, and by private organizations. The Department of Social Welfare administers legislation dealing with the protection of children, adoptions, family allowances, probation services, juvenile delinquency, the registration of welfare organizations, assistance to the blind, pensions, and poor relief. It subsidizes the voluntary work of about 1,800 registered organizations, including national bodies for cripple care, child welfare, the blind, the deaf, first aid, mental health, and maternal and family welfare. Church organizations also undertake relief and family welfare work.

In the provinces and municipalities, other services are financially assisted or provided in conjunction with hospitals, public health, education, and recreation (all races). Coordination of welfare services is effected by a statutory nonofficial national board and local boards.

Public health and medical services fall under a central Ministry of Health, the four Provincial Councils, and more than 700 local authorities. The Ministry of Health, created under the Public Health Act of 1919, has advisory and executive functions, chiefly in regard to the prevention and control of infectious and communicable diseases and the promotion of health. It has in its employ numerous full-time or part-time district surgeons in urban and rural areas. Health centres and clinics serve mainly the indigent. Larger municipalities have health departments and salaried medical officers. The provinces maintain public general hospitals, including homes for the chronically ill, for whites and nonwhites. These hospitals are financed from taxation, and in necessitous cases treatment is free or partly free. In addition there are many private, mission, mining, and industrial companies' hospitals. Medical-aid societies operate among sections of the public in a number of areas. In 1962 a central authority to coordinate this movement on a nationwide voluntary basis was established. By the 1960s South Africa had about 8,500 medical practitioners, mostly white but including a number of Bantu, Coloured, and Asian doctors.

6. Justice.—*Courts.*—The common law of the republic is based on Roman-Dutch law (*q.v.*), the uncodified law of Holland that was retained after the Cape's cession to Britain in 1806. The judiciary comprises a Supreme Court with local, provincial, and appellate divisions, the High Court, and circuit courts of South West Africa, and inferior courts. The judges, headed by a chief justice, are appointed by the state president-in-council; they cannot be removed from office except by an address of both houses of Parliament, and their salaries cannot be reduced. Appeals from the divisional courts and the high and circuit courts of South West Africa lie to the appellate division of 11 judges, with a quorum of 5 except where the validity of an act of Parliament is in question, when the quorum is 11.

The inferior courts comprise magistrates' courts, Bantu courts, and water courts (dealing with the use of water resources). Most civil and criminal litigation is a matter for the magistrates' courts, each responsible for a magisterial district. Regional magistrates are appointed in populous areas with criminal jurisdiction over a number of districts. The Bantu courts do not have jurisdiction over Bantu in criminal cases or where whites are involved.

Police.—The police are organized nationally into 11 divisions. The force comprises about 15,000 whites and a similar number of nonwhites, and it extends to South West Africa. Each division contains a number of districts and police-station areas. There are

also the security police, directly responsible to head office, and the traffic police of provincial and local authorities.

7. **Education.**—The Ministry of Education, Arts, and Science is responsible for primary and secondary education for white children who are physically handicapped or in need of care and for vocational schools, including technical high schools and colleges. It is also responsible for the autonomous universities of Cape Town (founded 1873), Natal (1909), Rhodes (1904), and the Witwatersrand (1922) (all English speaking), the Orange Free State (1855), Potchefstroom (1869), Pretoria (1930; from 1908 it was the Transvaal University College), Stellenbosch (1918) (Afrikaans speaking), Port Elizabeth (1965) (bilingual), and South Africa (a correspondence university). In 1965 it was decided to establish a new Afrikaans-speaking university on the Witwatersrand. In addition there are three university colleges for Bantu—Fort Hare, eastern Cape, for Xhosa (founded in 1916 for nonwhites; Bantu only since 1959); Zululand for Zulu only, at Ngoye (1959); and the University College of the North for Tsonga, Sotho, and Venda, at Turfloop, Pietersburg, Transvaal (1959); and one for Indians at Durban (1961). In 1959 the Department of Bantu Education assumed responsibility for all education of Bantu, whether primary, secondary, technical, teaching, or university, other than education in certain mission schools (which are subsidized and partly controlled except in the case of Roman Catholic schools). In the 1960s the Department of Coloured Affairs took over all Coloured education and the Department of Indian Affairs all Indian education.

The provinces administer all other primary and secondary education and teachers' training colleges (private schools excepted). Natal apart, local school committees are elected by parents, and elected and nominated district boards undertake general administration and (with the committees) select teachers. In Natal education is directly administered by the province. In all provinces schools for whites are generally single medium (*i.e.*, either English speaking or Afrikaans speaking), and school selection depends on the language in which the child is more fluent. Attendance is compulsory and free for white children between 7 and 16 years of age. For Coloureds and Asians, attendance is not compulsory but is free up to certain secondary standards, varying with the province. There are extensive bursary facilities for higher education. In 1963 the Ministry of Education established a National Advisory Education Council to foster a uniform national education policy.

8. **Defense.**—The South African Defense (Further Amendment) Act, 1961, provides that every white citizen at age 18 is subject (under an annual ballot) to nine months' compulsory military training for one year and another period of three weeks during the following two years.

The South African defense force comprises the permanent force, active Citizen Force, rifle commandos, reserves, school cadets, and auxiliary services (nonmilitary and nonwhite personnel). The permanent force consists of the Army, Air Force, and Navy organized in ten army commands, three air force groups, and two naval bases. It is staffed by regular personnel primarily concerned with training and administration. The active Citizen Force comprises personnel undergoing peacetime training, and the school cadets consist of boys between 12 and 17 years of age. (L. P. Gr.; L. H.; X.)

VII. THE ECONOMY

South Africa has passed through three phases in economic development. The first phase was the pioneer period of subsistence agriculture which lasted until about 1870, when the diamond fields were opened up. Gold discoveries followed, culminating in the development of the Witwatersrand gold field and giving a stimulus to agriculture and foreign exchange for the purchase of manufactured goods. With the outbreak of World War I and the inability to get supplies from overseas came the stimulus to manufacturing, ushering in the third phase, in which secondary industry became a greater producer of wealth than either agriculture or mining. This is reflected in the national income; between 1914 and 1953 manufacturing industries passed from eighth to first place among contributors to the national income.

The government's policy is to support private enterprise, with the minimum of interference. Governmental assistance is given in the fields of development, finance, and export promotion. The National Resources Development Council, set up in 1947, advises the minister of economic affairs in order to promote general development. There are a large number of regional development associations formed to guide local development. Foreign investments were heavy, especially after World War II, although in 1960 and 1961, because of racial unrest, the economy suffered from the outflow of foreign capital, which was later stemmed.

A. Production

1. **Agriculture.**—Agriculture has developed on a natural basis of climate, topography, and soil. Cultivation has flourished where ground is moderately flat, rainfall adequate or irrigation practicable, and the soils sufficiently fertile. Two parts of the country fulfill these requirements—the lowland surface of southwestern Cape Province, with winter rainfall exceeding 10 in. (255 mm.), and the eastern part, with summer rainfall exceeding 25 in. (635 mm.). In southwestern Cape wheat and grapes, with deciduous fruit trees, are important; in the eastern part maize (corn), sugar, and subtropical fruits are grown.

Livestock raising, while common in all crop-growing areas, is found mainly in the moister parts too high or too steep for cultivation or in areas of grassland too dry for cultivation. Many of these stock farms rely on underground sources of water for their animals, and through boreholes tap supplies in a variety of water-bearing rocks. Cattle are largely confined to the eastern summer-rainfall areas with long grass, sheep and goats to the drier areas where Karroo shrubs can withstand long droughts and provide adequate sustenance for small stock. Field crops and horticultural products are together of greater value than livestock products, though the value and volume of both sides has been steadily increasing. In the 1960s about 1,700,000 people were engaged in farming, including 120,000 whites.

Crops.—Maize (corn), the staple diet of the African, is the most valuable of the republic's crops. Two kinds are generally grown: white dents and yellow flints. About 6,000,000 morgen (12,700,000 ac.) are sown to maize, the production fluctuating between about 40,000,000 bags (of 200 lb.) and 50,000,000. Excess of production over local requirements has necessitated exports involving considerable annual losses. This is one of the republic's problems, since production is likely to increase as more hybrid seed becomes available. Wheat is grown mainly in southwestern Cape, and also in eastern Orange Free State and, under irrigation, in southern and central Transvaal. Annual production has varied from about 5,000,000 to 11,700,000 bags. As the Bantu are buying more wheat bread, an annual import of wheat is generally necessary. Sugarcane growing is limited mainly to the east coastal area of Natal (including Zululand). The subtropical climate necessitates a 16- to 20-month reaping cycle. About 550,000 ac. are under cane, of which about 290,000 ac. are harvested each season. Production is about 1,400,000 short tons of sugar from 12,000,000 tons of cane, of which about 800,000 tons are consumed locally. Exports, which vary greatly with world demand, average about 600,000 short tons. Other important crops include tobacco, peanuts, potatoes, and kafir (sorghum).

Fruit.—The gross value of the annual production of fresh and dried fruit is about R. 99,000,000 (£49,500,000 or $138,600,000). Deciduous tree fruits and grapes flourish best in southwestern Cape, citrus and subtropical fruits in the eastern part of the republic. The main deciduous tree fruits grown are (in order of quantity exported) apples, pears, plums, peaches, and apricots. Exported grapes total approximately 32,000 short tons, and 4,000,000 gal. of wine and a smaller quantity of brandy are also exported. More than 80% of the citrus grown consists of Valencia and navel oranges; grapefruit, lemons, and naartjies (tangerines) are grown in much smaller quantities.

Livestock.—The livestock population comprises mainly cattle, sheep, and goats, with comparatively small numbers of pigs and donkeys and much poultry. Cattle number about 12,000,000; approximately 4,000,000 are in Cape Province (mainly in the eastern part), 4,000,000 in Transvaal, 2,500,000 in Natal, and nearly 2,000,-

000 in Orange Free State. Of these about 7,000,000 belong to whites, 1,200,000 to Bantu on white farms, and 3,800,000 to Bantu in the homelands. Sheep number approximately 38,000,000, of which nearly 25,000,000 are in Cape Province, nearly 9,000,000 in the Free State, nearly 4,000,000 in Transvaal, and over 1,000,000 in Natal. About 28,000,000 of these are merinos, 1,200,000 karakuls, and 4,000,000 nonwooled sheep. About 3,500,000 of the nonmerino sheep belong to Bantu. Goats number nearly 5,500,000, more than 3,500,000 being in Cape Province, 900,000 in Natal, 650,000 in Transvaal, and 85,000 in the Free State. Of these about 870,000 are angora goats. About 3,000,000 goats are Bantu owned.

Cattle products include meat, fresh milk, butterfat, cheese milk, and milk for condensing. Products from sheep and goats include not only meat and milk (from goats) but wool and mohair. Miscellaneous livestock products include ostrich feathers.

2. Forestry.—Out of the republic's total land area of slightly over 302,000,000 ac. (122,200,000 ha.), natural forest covers less than 925,000 ac. (374,000 ha.). There are more than 3,000 timber and wattle plantations varying from 25 to over 10,000 ac. (4,000 ha.). Of the large plantations (5,000 ac. or more) most are in eastern Transvaal, Natal, southern Cape Province, and Zululand. In the natural forests the most valued hardwoods are stinkwood and sneezewood. The softwoods include the yellowwoods, the Cape box, and many others. The natural forest is carefully preserved by the state Forestry Department, and only small quantities of timber are cut each year. The chief broadleaf species include eucalyptus, matchwood poplars, and the tan wattles. An important factor in the development of exotic softwood plantations is the high natural wood increment, one of the highest in the world (the average annual increment is of the order of 150 cu.ft. per acre, which may be compared with European and North American areas where it is between 17 and 35 cu.ft.). In some of the wetter afforested areas in South Africa the average increment is 250 cu.ft. per acre. South Africa's afforestation potential is estimated to be about 2,000,000 ac.

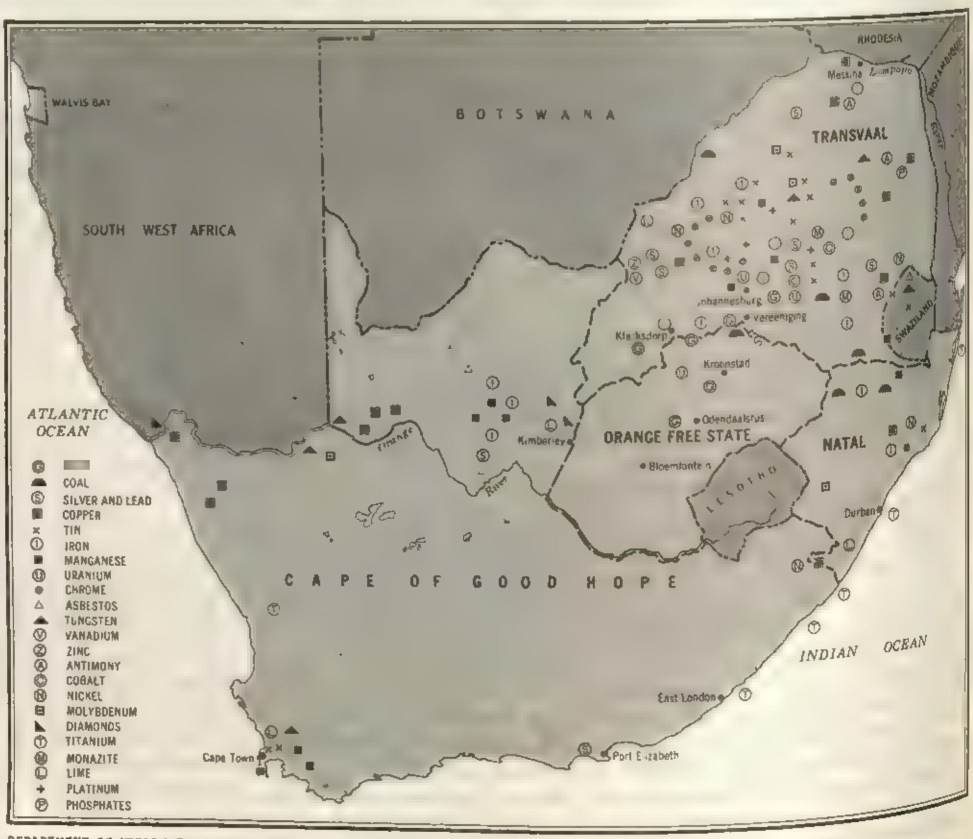
The annual national consumption of softwoods is about 130,000,000 cu.ft. of logs. Of this about one-quarter is imported while three-quarters is produced locally. Since, however, pines take 30–40 years to mature, and well over half of the plantations have been planted since 1950, 75% of the logs delivered to the sawmills are immature. The local woods are therefore generally marketed at prices 15%–25% below those of imported timber, but mature South African timber compares favourably with the imported wood. The export of forest products includes wattle bark and bark extract. (*See* also *Physical Geography: Vegetation*, above.)

3. Fisheries.—Marine fishing is carried on mainly off the west and south coasts. The west coastal waters with their low temperatures and abundant marine plankton abound in fish life and provide the largest catches. Off the west coast the most profitable types of fishing are inshore shoal fishing and offshore trawling. The two principal shoal fish are the pilchard and the maasbanker, with mackerel varying considerably in quantity. Trawling is the main source of fresh fish consumed locally. Stockfish, or Cape hake, is by far the most important item in the trawled catch, though much smaller catches are taken of the 14 or 15 other varieties, of which the most valuable are kingklip, the Agulhas sole, panga, and kabeljou. Most of the catch of line fisheries is of snoek, or sea pike, the remainder consisting mainly of geelbek (Cape salmon), kabeljou, steenbras, redfish, and sharks. Vitamin A is derived from the shark livers and there is an export of dried and salted shark meat to the Far East. An important item in the inshore catch is the crayfish, commercially termed rock lobster, which is found mainly off the west coast and is exported largely to the United States in the form of frozen tails and canned lobster. There is a whaling industry based on Durban and Saldanha Bay. Fin, sperm, sei, humpback, and blue whales are caught for whale oil, sperm oil, whale meat and meat extract, and vitamin oil.

4. Minerals.—Mining provided in the 1960s the second largest contribution (after manufactures) to the national income. Production of gold bullion exceeded 29,000,000 fine oz. annually and provided a revenue of more than R 730,000,000 (£365,000,000 or $1,022,000,000). Most of the output came from the 55 producing mines controlled by the Transvaal and Orange Free State Chamber of Mines. In decreasing order of production the seven main gold fields are Orange Free State, Far West Rand, Klerksdorp, East Rand, Central Rand, Evander, and West Rand. All of these mine the "reefs" or gold-bearing conglomerates of the Witwatersrand geological system, which has surface outcrops on the Witwatersrand but is found mostly at depth in the other gold fields. On the Rand (*i.e.*, Witwatersrand) the main reef dips gently southward and is mined to a depth of over 11,000 ft. (3,350 m.).

Since 1952 uranium, which in the form of uraninite is associated with the gold in the reefs, has been produced in ever increasing quantities. The republic's uranium ore reserves are estimated at 1,100,000,000 tons, of which the uranium content appears to be greater than the reserves of Canada or the United States. Nineteen of the older mines, though producing gold at a loss, make a substantial profit on uranium.

Employment on the gold mines includes about 51,000 whites and 400,000 Bantu drawn from many parts of southern Africa. The place of gold in the economy of the republic is well established, but perhaps its most important effect is as a stabilizer in the fluctuations of foreign trade (see *Foreign Trade*, below).



DEPARTMENT OF INFORMATION, SOUTH AFRICAN EMBASSY, LONDON

PRINCIPAL MINERAL DEPOSITS IN THE REPUBLIC OF SOUTH AFRICA

Of other precious minerals, platinum is produced as the market demands; the annual output is valued at about R 16,000,000. Small quantities of silver and osmiridium are found in the gold ore. Diamonds to the value of about R 44,000,000 are derived from mines and alluvial deposits. In the base mineral group coal from the Ecca beds of the Karroo system is mined in southern Transvaal and Natal; in the 1960s the output exceeded 49,000,000 tons annually, of which nearly 1,000,000 tons were exported. Iron ore production, mainly from Thabazimbi in Transvaal, Postmasburg in northern Cape Province, and from northern Natal, fluctuated between 5,000,000 and 6,000,000 tons, the bulk of the ore being a hard, high-grade hematite with low phosphorus and sulfur content. Other minerals include asbestos, copper, manganese, chrome ore, and tin.

5. Power.—In 1922 the South African government established the Electricity Supply Commission (ESCOM), a nonprofit-earning body, to control and supply power for the industrial development of South Africa. The commission operates in eight licensed areas of supply: Rand and Orange Free State, Cape Western, Cape Eastern, Natal Southern, Natal Central, Border, Eastern Transvaal, and Cape Northern areas. The total power output of the commission in the 1960s was in excess of 22,000,000,000 kw.hr., representing about 70% of the country's output, the rest being provided by municipalities and private undertakings (mines and industries). The supply to rural settlements and farms has steadily increased. The power stations, with two small exceptions, are all thermal, coal-burning types.

6. Industries.—Government-sponsored industrial activities include the South African Coal, Oil, and Gas Corporation (SASOL), brought into being for the extraction of oil from coal; the Iron and Steel Industrial Corporation, Ltd. (ISCOR), which owns furnaces and mills and provides about two-thirds of the country's steel requirements; Klipfontein Organic Products (KOP), which produces chemicals and insecticides; and the Phosphate Development Corporation, producing fertilizers. Industrial research is sponsored by the South African Council for Scientific and Industrial Research (CSIR), a corporate body set up to advise the minister of economic affairs on all questions of scientific and technological methods affecting the utilization of the natural resources of the republic. The CSIR controls the Bureau of Standards and a number of national laboratories including those for research in chemistry, physics, telecommunications, building, mechanical engineering, road construction, personnel administration, nutrition, and industries. An important function of the council is the promotion of cooperative research by the formation of industrial research associations which are independent bodies subsidized by the council.

Manufacturing is by far the largest item (about 85%) of all private secondary industry, while building construction, electricity, gas and steam, and services make up the remainder. In the manufacturing sector four areas are outstanding in importance: southern Transvaal (including Pretoria, Vereeniging and Vanderbijlpark), western Cape, Durban-Pinetown, and Port Elizabeth-Uitenhage.

Of the total gross output of private manufacturing, the groups producing most were: food, metal products, clothing and footwear, basic metal industries, chemicals and chemical products, and nonmetallic mineral products. The total number of employees in manufacturing industries in the 1960s exceeded 830,000, comprising about 26% whites, 57% Bantu, and 17% Asians and Coloureds.

B. Trade and Finance

1. Foreign Trade.—A characteristic feature of South Africa's trade has been a constant disequilibrium between the import and export of merchandise, excluding gold. In 1925, for example, the excess of imports over exports, excluding gold, was £12,800,000; in 1930, £17,100,000; in 1935, £44,300,000. In each year the deficit was changed into a surplus by exports of gold bullion amounting respectively to £34,300,000, £35,900,000, and £71,400,000. Gold is therefore of increasing importance in the balance of payments.

Although South Africa is no longer a member of the Commonwealth of Nations, preferential tariff rates are maintained with Great Britain under a bilateral agreement and in the framework of the General Agreement on Tariffs and Trade (GATT).

Imports.—In the 1960s by far the most valuable item was the class "metals, metal manufactures, machinery, and vehicles." In this class the chief commodities were automobiles and trucks, railway locomotives and rolling stock, tractors and parts, and airplanes. These goods were supplied by the U.K. and other Commonwealth countries; of the other suppliers the U.S. and West Germany far exceeded the other trade partners (Japan, Italy, the Netherlands, Rhodesia, France, Belgium, and Ceylon). Second in value was the class "fibres, yarns, textiles, and apparel." Third in value came "oils, waxes, resins, paints, and varnishes," with crude oil, paraffin, and motor spirit (gasoline) from Iran as the main items. Next in value were "drugs, chemicals, and fertilizers," "foodstuffs," "minerals, earthenware, glassware, and cement," and "wood, cane, and wicker manufactures."

Exports.—In the 1960s the class with the highest value (excluding gold) was "metals, metal manufactures, etc." Atomic energy material covered almost half of this amount. Other minerals were of comparatively small value: copper, lead ore concentrates, manganese ore, chrome ore. Manufactured metal goods include mining machinery, ferroalloys, wrought iron, and manufactured iron and steel. Small items deriving from gold mining were silver and osmiridium. Foodstuffs came second, the chief items being fresh and preserved fruits (citrus exports go to more than 35 countries), maize (corn) and maize meal, fish (fresh, dried, frozen, and fish meal), and sugar. The class "animals, agricultural and pastoral products" was next in value. The most important commodities in this class were wool, hides and skins, fish meal, wattle and wattle bark extract, and mohair. Minerals, earthenware, and glassware came next (diamonds, asbestos, etc.), followed by jewelry (cut and polished diamonds), then by oils, waxes, etc., and other commodities of small value.

The chief trading partners receiving exports and reexports were the United Kingdom, Rhodesia, the United States, Japan, West Germany, Italy, Israel, Belgium, France, and the Netherlands.

2. Banking and Currency.—In South Africa the Ministry of Finance determines the country's general financial policy, which is administered by the central bank and operated mainly by the commercial banks and other specialized financial institutions. The central bank is the South African Reserve Bank, which came into existence in 1921 during the monetary chaos that followed World War I. The bank is a privately owned joint-stock company with limited liability; its governor and deputy governor and three other directors on the board of 11 are appointed by the government. The bank has the sole right of note issue in the republic, but its notes are not redeemable in gold.

Under the terms of the South African Reserve Bank Act of 1944 the bank was required to maintain in gold coin and bullion a reserve of at least 30% of the aggregate amount of its note issue and of its other liabilities to the public, but by an amendment in 1948 the minimum reserve ratio of the bank was reduced to 25%.

The commercial banks are required to hold on deposit with the Reserve Bank balances amounting to not less than 10% of their demand liabilities payable in the republic and 3% of their time liabilities. The Reserve Bank, however, is empowered to require the commercial banks to maintain, when the national interest demands it, supplementary reserves not exceeding 10% of their total liabilities to the public. The Reserve Bank found it necessary in the national interest to exercise these powers in 1958. The Reserve Bank may alter the supplementary reserves to 6% to ease a strain on the banking system. Registered banking institutions include commercial banks, people's banks, loan banks, and deposit-receiving institutions.

To promote agricultural development the Land and Agricultural Bank of South Africa was established in 1912 as a nonprofit-making institution. To promote an active money market the National Finance Corporation of South Africa was established in 1949. A close cooperation with the Reserve Bank is provided for, and the corporation may not be placed in liquidation except by an act of Parliament.

Currency.—The South African coinage was decimalized in 1961 when the rand (issued as two gold coins of R 1 and R 2) became the new monetary unit equal to the former half-pound (10 shillings or $1.40). The new silver coins were 50 cents (crown), 20 cents (florin), 10 cents (shilling), and 5 cents (sixpence); and the bronze coins comprising the cent (twelve-tenths of a penny), the two-cent, and half-cent. Although no longer a member of the Commonwealth, South Africa remains within the sterling area.

3. National Finance.—Exchequer receipts fluctuated in South Africa from £147,400,000 (equivalent to R 294,800,000) in 1950 to R 1,088,000,000 by the mid-1960s; in the same period exchequer issues increased from R 293,600,000 to more than R 1,018,000,000. On the revenue account (in excess of R 600,000,000) the receipts were derived from customs and excise, post office, and inland revenue. Of these the inland revenue amount was by far the largest, with income tax the highest source of revenue, followed by departmental receipts, interest and dividends, transfer duty, and nonresident shareholders' tax.

Parallel expenditure from the revenue account included, as its main items, provincial administration, social welfare and pensions, posts and telegraphs, defense, public debt, and agriculture.

In the decade following 1954 the net national income increased from R 3,025,000,000 to around R 5,600,000,000. The main sources were manufacturing, mining, agriculture, forestry and fishing, and transport.

The Bantu homelands five-year plan (1961–66) called for a total estimated expenditure of R 114,000,000.

C. Transport and Communications

1. Roads.—In South Africa the construction and maintenance of roads is the responsibility of provincial administrations. In each of the provinces four classes of roads are recognized: national, main, district, and minor roads. Provincial main roads are 80 ft. (24 m.) wide and, in general, are of the all-weather type, with gravel or bituminous surface. District roads, 60 ft. (18 m.) wide, are usually of the fair-weather type, with gravel surface. Minor roads vary from almost veld tracks to ordinary farm roads. The extent of such road types is of the order of 13,000 mi. of blacktop (bituminous, asphalt, tarmac, etc.), 39,000 mi. of gravel-surfaced, and 150,000 mi. of earth roads.

In 1935 the National Roads Act created a National Road Board for the administration of national roads under the responsibility of the central government. The board's program, announced in 1936, provided for the construction, reconstruction, and repair and maintenance of about 5,120 mi. of roads, declared "national." These were specified as bituminous surfaced with a minimum width of 100 ft. Fifteen routes were designated, their function being to link together the larger centres and to facilitate communication with adjoining territories. Thus route no. 1 links Beitbridge (over the Limpopo River on the Rhodesian border) with George on the south coast, passing through Pretoria, Johannesburg, and Bloemfontein; route no. 2 links Cape Town with Durban, passing through Mossel Bay, Port Elizabeth, and East London; route no. 3 links Johannesburg with Durban; route no. 4 links Pretoria with Komatipoort on the Mozambique border. The remaining routes interconnect these four routes or provide branch roads or extensions to other important centres.

2. Railways.—With few exceptions the railways and harbours of South Africa and South West Africa are the property of the government, the control and management being under the direction of the South African Railways and Harbours Administration, responsible to the minister of transport. Of the republic's 12,000 mi. of railway lines, 5,000 mi. are main lines of 3-ft.-6-in. gauge, and nearly 7,000 mi. are branch lines, of which less than 500 mi. are of 2-ft. gauge. Connected with the railways are the South African Railways' auxiliary road motor services, which cover almost 32,000 route miles.

Electrification of South Africa's railways has taken place mainly in industrial areas as, for example, southern Transvaal, where, in addition to electrification on the Witwatersrand and between Johannesburg and Pretoria, the lines from the coal mines of the Witbank area are connected by electrified lines with Kroonstad and the Free State gold field. In Natal the main line has been completely electrified from Durban to the Transvaal border, and in southwestern Cape the line to the interior has been electrified for 330 route mi. (530 km.) to Beaufort West. In the republic 1,684 route mi. were electrified by the mid-1960s. Diesel locomotives are replacing steam chiefly for traction in the drier parts of the country and in South West Africa.

3. Shipping.—There were about 470 ships registered in the mercantile marine in the 1960s with a registered gross tonnage of about 285,000. The total number of ships arriving at South and South West African ports in a year was nearly 15,000, including coasters. In respect of cargo Durban is the first port in the republic and in Africa, followed in South Africa by Cape Town, Port Elizabeth, and East London. Ship arrival and passenger transits are also greater at Durban than at the other South African ports.

A marked feature of shipping in South Africa is the large number of foreign cargo- and passenger-carrying liners calling regularly at ports either as destination or in transit to other parts of the world. There is thus generally ample transport for South Africa's overseas imports and exports. Since, however, precooling is essential for the country's important fruit exports, the large precooling stores at Cape Town and Port Elizabeth have special significance. An important feature of Cape Town harbour is the Sturrock graving dock, which is able to accommodate even the largest oil tankers.

4. Air Transport.—South African Airways is included in the South African Railways and Harbours Organization and is the only operator with regular services. There are more than 270 licensed civic airports in South Africa. Of these, however, Jan Smuts Airport (Johannesburg) is the only one of international standard; four others are of national standard. Services are classified as domestic, regional (Johannesburg-Rhodesia-Mozambique), and international (Johannesburg-London, Johannesburg-Australia).

5. Postal Services and Telecommunications.—These are maintained at about 3,150 post offices, 1,580 of which are also money-order offices. The post office has a savings bank and also issues listeners' radio licences.

Included in telephone services are more than 90,000 farm connections. Besides internal telephones there are radiotelephone services to foreign countries and ships at sea. A radiotelegraph and telephone system between South Africa and South West Africa was introduced in 1960. There are more than 1,070 departmental teleprinters in use, and country offices equipped for teleprinter working total over 240. Twenty-two radioteleprinter subscriber circuits are in operation to overseas countries, while international telex service is available via London to 59 overseas countries.

Domestic radio transmission is controlled by the South African Broadcasting Corporation, a public utility established in 1936, which is responsible to the Minister of Post and Telegraphs and derives its revenue from listeners' licences and from its commercial service (Springbok Radio). There are 28 broadcasting stations transmitting three national programs, English, Afrikaans, and commercial. Bantu services are broadcast on the first two of these. There is no television service.

SOUTH AFRICAN LITERATURE. The earliest writings about South Africa, the country, and its inhabitants, date back several centuries, but South African literature—the work of authors who were born in South Africa, or have lived there and identified themselves with South African thought and life—is of more recent origin because the turmoil of South African affairs prevented any serious creative writing before the 19th century. After a difficult start in its development from the Dutch language, Afrikaans also produced a strong literature of its own, and a review of South African literature must be divided into that written in English and that in Afrikaans.

IN ENGLISH

Some critics hold that English literature in South Africa has followed the main lines of development in other English-speaking countries. This view should be accepted with reservations. It is true that many early writers were British, and that many writers in the 20th century left South Africa, so that their work belongs to other traditions; nevertheless it is also true that South African literature in English has a character of its own.

Poetry.—In poetry this individuality is revealed by an indigenous subject matter and the use of imagery and diction that are characteristically South African. The first poet of note was a Scot, Thomas Pringle (1789–1834), who spent six years in South Africa and later published *Ephemerides* (1828) and *African Sketches* (1834). After a considerable interval there were William Charles Scully (*The Wreck of the Grosvenor*, 1886; *Poems*, 1892), Francis Carey Slater (*Footpaths Thro' the Veld*, 1905; *Settlers and Sunbirds*, 1919; *The Karroo*, 1924), the Rev. Arthur Shearly Cripps (*Lyra Evangelistica*, 1911; *Pilgrimage of Grace*, 1912; *Lake and War*, 1917), and another Scot, Charles Murray (*Hamewith*, 1909; *A Sough o' War*, 1917; *In the Country Places*, 1920). These are poets of the older school, and their verse is of no particular interest except for its "South African" quality. Cullen Gouldsbury (*Songs out of Exile*, 1912; *From the Outposts*, 1914), a poet and novelist of great promise, died at 35, before he had fulfilled it.

The first poet to combine this distinctive "South African" quality with an outstanding poetic gift was Roy Campbell (*q.v.*; 1901–57). William Plomer (1903–) also became prominent with *The Family Tree* (1929) and *Selected Poems* (1940). Later poets include Frank Prince, Rico Martin Titlestad, Anthony Delius, and Guy Butler.

Prose.—Travel books and "letters home" were the earliest prose works written about South Africa, and the works of Thomas Baines, John Barrow, William John Burchell, and David Livingstone (*q.v.*) became well known in the 19th century. The letters of Lady Anne Barnard (*q.v.*), edited as *South Africa a Century Ago* (1901), give a vivid account of the years 1797–1801 at the Cape.

The South African novel has characteristics that differentiate it from other novels in English. Almost all novels deal with topics peculiar to South Africa, although notable exceptions are the first and most famous South African novel, *The Story of an African Farm* (1883), by Olive Schreiner (*q.v.*); *Mary Glenn* (1925), *Sons of Mrs. Aab* (1931), and *What Hath a Man?* (1938) by Sarah Gertrude Millin (*q.v.*); Ethelreda Lewis' *The Harp* (1924); and Elizabeth Charlotte Webster's *Expiring Frog* (1946), all of which deal with problems of general, rather than particular concern. The most popular subject is the trials of the "mixed," or in official definition, Coloured, people, who have been isolated from both black and white persons (*see* further SOUTH AFRICA, REPUBLIC OF: *History*). Sarah Gertrude Millin has become the major writer of this theme. The subject is also treated by William Plomer in his short stories *I Speak of Africa* (1927); and by Laurens van der Post (1906–), in *In a Province* (1934). Peter Abrahams (1919–), a Coloured writer, produced impressive work in *Dark Testament* (1942), *Song of the City* (1945), *Mine Boy* (1946), and *Return to Goli* (1953).

The African has formed the subject of hundreds of novels, from

adventure stories to studies of race relations. Powerful work has been produced by William Plomer (*Turbott Wolfe*, 1925), Sarah Gertrude Millin (*The Coming of the Lord*, 1928; *The Herr Witchdoctor*, 1941), Alan Paton (*Cry, the Beloved Country*, 1948; *Too Late the Phalarope*, 1953), and Dan Jacobson (*The Trap*, 1955; *A Dance in the Sun*, 1956; *The Price of Diamonds*, 1957; *The Evidence of Love*, 1960), who all studied race relations as they affect the individual; and Harry Bloom (*Episode*, 1956; *Whittaker's Wife*, 1962), Nadine Gordimer (*The Lying Days*, 1953), Stuart Cloete (*The Mask*, 1958; *Rags of Glory*, 1963), and Eugene O'Donnell (pseudonym of Laurence James McCauley; *The Night Cometh*, 1960), who all wrote of the political implications of racial problems. Other novels include historical works by Stuart Cloete (*Turning Wheels*, 1937; *Watch for the Dawn*, 1939; *The Hill of Doves*, 1942) and Dorothea Fairbridge (*That Which Hath Been*, 1910); A. A. Smith's *Trader Horn* (1927–28); Percy Fitzpatrick's charming dog story *Jock of the Bushveld* (1907); Horace Rose's *Golden Glory* (1915); and Daphne Muir's *A Virtuous Woman* (1929).

Pauline Smith's *The Little Karroo* (1925) must head any list of South African short stories. William Westrup (d. 1943) and Ernest Glanville (1856–1925) are noteworthy for their tales of animal and veld. Later, Herman Charles Bosman (*Mafeking Road*, 1947) and Nadine Gordimer (*The Soft Voice of the Serpent*, 1953; *Six Feet of the Country*, 1956; *Friday's Footprint*, 1960) became leading exponents of this genre. Other authors who have written short stories are Sarah Gertrude Millin (*Two Bucks Without Hair*, 1957), Stuart Cloete (*The Soldiers' Peaches*, 1959; *The Looking Glass*, 1963), and Jack Cope (*The Tame Ox*, 1960).

No significant drama in English had been produced in South Africa by the mid-20th century. (J. P. L. S.)

IN AFRIKAANS

Afrikaans, one of the youngest members of the Germanic group of languages, and a derivative of 17th-century Netherlandic (*see* NETHERLANDIC LANGUAGE), is the language used by the descendants of Dutch, German, and French colonists who settled in South Africa after 1652 and before the British occupation in 1806. Although the Afrikaans vocabulary is almost identical with the original Netherlandic stock, the grammatical structure has been much simplified. In Afrikaans the noun has no grammatical gender and has lost all inflectional forms except the singular and plural; and the verb has one form for all persons, expresses the tenses by means of modal words, and has lost the difference between strong and weak conjugations. The main traits of Afrikaans were probably present by *c.* 1750.

Toward mid-19th century Afrikaans was used in letters, in some newspapers, and in a few pamphlets, but until the 1920s Dutch (Netherlandic) was still used for literary and official purposes. In 1875 a society, Die Genootskap van Regte Afrikaners, was founded to translate the Bible into Afrikaans and to foster official use of the language. The society founded a monthly magazine, *Die Afrikaanse Patriot*, and started a printing press; but of the literary production of the period 1860–1900 only the Rev. J. L. Cachet's didactic stories, collected as *Sewe Duiwels* (1907), the Rev. S. J. du Toit's historical novel *Di Koningin fan Skeba* (1898), and F. W. Reitz's adaptation of Burns's "Tam o' Shanter" (*"Klaas Geswint en sy Perd,"* 1870) are still read.

The South African War (1899–1902) saw the end of Die Genootskap van Regte Afrikaners, but also the birth of a new spirit in the movement for the recognition of Afrikaans. Phonetic orthography was discarded in favour of a spelling more closely related to Dutch; new writers and scholars took the lead in promoting the use of the language; new journals were founded. Die Afrikaanse Akademie was founded in 1909. As a result of these activities Afrikaans replaced Dutch in schools (1914), university professorships in Afrikaans were instituted, and by 1924 the churches had adopted Afrikaans. In 1925, under the premiership of J. B. M. Hertzog (*q.v.*), Afrikaans was made an official language. The Afrikaans version of the complete Bible was published in 1933, and the first volume of the Afrikaans standard dictionary, begun in 1925, was completed in 1950 (by 1961 vol. iv [H.-I.] had appeared). After 1935 an increasing number of Afrikaans journals, magazines, and newspapers was established.

A literature distinctively Afrikaans in outlook and sentiment grew out of the experience of the South African War. The first poets of real merit whose poems arose from this experience were Eugène Nielen Marais (1872–1936), Johannes François Elias Celliers (1865–1940), Jakob Daniel du Toit (*q.v.;* 1877–1953), and C. F. L. Leipoldt (*q.v.;* 1880–1947). The poem that brought fame to Celliers was *"Die Vlakte"* ("The Plain"; 1908), while Marais made his mark as a poet with outstanding nature-studies. Largely because of the national spirit of this poetry, Afrikaans very soon came to be recognized as the cultural language of South Africa.

This led to a renewed vigour in prose writing, and, although Dutch authors still influenced many novelists, a sound contribution to the beginning of a mature Afrikaans prose style was made by Cornelis Jakob Langenhoven (1873–1932), Gustav Schoeman Preller (1875–1943), Daniel François Malherbe (1881–), and Jochem van Bruggen (1881–1957). While still largely concerned with the national experience of the war, these writers were turning their attention to the realistic and psychological novel. The best examples are Malherbe's *Die Meulenaar* (1926) and van Bruggen's *Ampie* (1924–42), a trilogy on the poor-White problem. Van Bruggen's work as a whole—and especially *Die Sprinkaanbeampte van Sluis* (1933), which was less popular, but of greater literary merit, than *Ampie*—profoundly influenced contemporary novelists. A. A. Pienaar's short stories on wild life in the African jungle, *Uit Oerwoud en Vlakte* (1921), also belong to this period.

Meanwhile younger poets, primarily concerned with the impact of modern science and technology on a mainly agrarian and patriarchal culture, began to write, and the stress shifted from national to personal experience. F. P. (Toon) van den Heever (1894–1956) especially in his *Gedigte* (1919), embodied his doubt, and his rebellion against the religion of his people. Although characterized by differences of outlook, style, and interests, the following verse also belongs to this period: T. J. Haarhoff, *Die Liefde van Catullus* (1933); S. J. du Toit, *Tussen die Dae* (1947); A. G. Visser, *Gedigte* (1925), and *Die Purper Iris* (1930).

About 1925 a new group emerged to dominate the literary scene for the next decade. The most marked advance was in the novel and short story, the realistic and the social novel being particularly favoured. The outstanding figure was Christiaan Maurits van den Heever (1902–57; *Op die Plaas*, 1927; *Droogte*, 1930; *Somer*, 1935; *Laat Vrugte*, 1940; *Die Held*, 1948; and a biography, *Generaal J. B. M. Hertzog*, 1943). Other prominent authors of this group were C. H. Kühn, also known as Mikro (*Toiings*, a trilogy, 1934; *Klaradynstraat*, 1947), Johannes van Melle (*En Ek is Nog Hy*, 1942; *Verspeelde Lente*, 1961), the brothers G. C. and S. B. Hobson (*Kees van die Kalahari*, 1929; *Buks*, 1933), Holmer Johanssen (*Die Onterfdes*, 1944), P. J. Schoeman (*Op die Groot Spore*, 1942), and G. H. Franz (*Moeder Poulin*, 1946). Those of this group who were also poets—van den Heever (*Deining*, 1932; *Aardse Vlam*, 1938) and I. D. du Plessis (*Stryd*, 1935; *Kwatryne*, 1941)—might be regarded as the transition to the next generation, the poets of 1935.

In the poetry of this latter group national experience is at last ignored, and the poems centre on personal feeling. Rhyming verse is discarded in favour of modern experiments. The new form of poetry passed its zenith soon after 1950, but until then it was predominant, the outstanding writers being N. P. van Wyk Louw (*Alleenspraak*, 1935; *Die Dieper Reg*, 1938; *Raka*, 1941), D. J. Opperman (*Heilige Beeste*, 1945; *Negester oor Ninevé*, 1947; *Engel uit die Klip*, 1951), and W. E. G. Louw (*Die Ryke Dwaas*, 1934), one of the founders of the important periodical *Standpunte* (1945–). At the same time, more lyrical poetry was being written by Uys Krige (*Oorlogsgedigte*, 1942; *Hart Sonder Hawe*, 1949), Elisabeth Eybers (*Belydenis in die Skemering*, 1936; *Die Stil Avontuur*, 1939), S. J. Pretorius (*Vonke*, 1944; *Inkeer*, 1948), and Olga Kirsch (*Mure van die Hart*, 1948).

As yet Afrikaans has few dramatists of merit, the most noteworthy being C. F. L. Leipoldt (*Die Heks*, 1923), J. F. W. Grosskopf (*Die Klipdolk, en ander Kortspele*, 1941), Henry Allan Fagan (*Die Ouderling*, 1934), and Uys Krige. Younger dramatists are

W. A. de Klerk (*Die Jaar van die vuur-os*, 1952) and G. J. Beukes (*As ons twee Eers getroud is!*, 1952). An interesting interlude came with two verse-dramas in the classical style: D. J. Opperman's *Periandros van Korinthe* (1954) and N. P. van Wyk Louw's *Germanicus* (1956).

Quite a stir has been caused by avant-garde novels, stimulated by English and French models. Of these, *Lobola vir die Lewe* (1962) by André Brink, and *Sewe Dae by die Silbersteins* (1962) by Étienne Leroux, are worthy of note. (A. J. Ce.)

SOUTH AFRICAN WAR, also known as the Anglo-Boer War or Boer War, was fought between Great Britain and the two Boer republics, the South African Republic (Transvaal) and the Orange Free State, between October 1899 and May 1902.

Causes.—The war had its origins in the relations that had developed between Britain and the South African Republic. Britain, especially after 1895, when Joseph Chamberlain became colonial secretary, aimed at establishing its supremacy over southern Africa and at preventing the encroachment of its colonial rivals, France and Germany, while Paul Kruger (*q.v.*), president of the South African Republic, was determined to maintain the political and economic independence of his Boer republic. Several factors helped build up the tension that ultimately led to war. The first of these was the issue of British suzerainty. In 1877 Britain annexed the Transvaal, but in consequence of a Boer rebellion (December 1880) and the defeat of British troops at Majuba (February 1881), by the Pretoria Convention (August 1881) the Transvaal was granted self-government subject to the suzerainty of Queen Victoria; three years later, by the London Convention (February 1884), it received a fuller measure of independence (*see* Transvaal: *History*). But Britain's retention of control over the republic's treaties, other than with the Orange Free State, and its claim at a later stage that it had not abandoned suzerainty were a source of resentment to Kruger and his burghers (enfranchised citizens).

The second factor was the influx of large numbers of immigrants (known as *uitlanders*), who came into the republic from Britain and elsewhere following the discovery of gold on the Witwatersrand in 1886. Although they paid the bulk of the republic's taxation, they were denied any effective share in the government; the English language was banned in the law courts and schools; and juries consisted only of burghers. The *uitlanders* also complained of the government's grant of monopolies in dynamite and other commodities vital to the mining industry and of corruption on the part of the officials. But Kruger, fearing that if given political rights the *uitlanders* might gain control of the Boer republic, rejected their demands for the franchise and for redress of their grievances.

The third factor was the conflict between Kruger's ideal of independence and isolation and the attempts of Cecil John Rhodes (*q.v.*), head of the British South Africa Company (which had control over the country north of the Limpopo River) and prime minister of the Cape Colony, to bring about an economic federation of the whole of southern Africa that would lead to a political federation under the British flag. The British occupation between 1885 and 1895 of territory to the north, west, and east of the republic, which encircled it and cut it off from access to the sea, aroused the fears of Kruger. He resisted Rhodes's attempts to include the republic in a customs union, and to ensure economic independence from the British colonies to the south he gave Hollander interests a concession to build a railway line from Pretoria to Delagoa Bay in Portuguese East Africa. A fierce rivalry in railway rates developed between the Netherlands Railway Company, which was responsible for this line, and the Cape authorities. War seemed imminent when in October 1895 Kruger closed the Vaal River drifts (fords) that the Cape authorities had been using to send goods into the Transvaal by wagon to avoid the high rates imposed on the Transvaal section of their Cape to Johannesburg line; but under pressure from Chamberlain, Kruger reopened the drifts on Nov. 7.

The Jameson Raid.—Hostility between the Boers and the British was further increased by the fiasco of the Jameson Raid (December 1895). Rhodes arranged that L. S. Jameson should lead an armed force into the republic from Pitsani, in Bechuanaland, to support a rising of the *uitlanders* against the Kruger government. The rising failed to materialize, and Jameson's raid ended in his capture at Doornkop (Jan. 2, 1896), but it aroused among the Boers deep suspicion of Britain's intentions. (*See* Jameson, Sir Leander Starr.) Kruger, convinced that war with Britain could be only a matter of time and, by receiving a congratulatory telegram from the German emperor, William II, encouraged to hope for German assistance in the event of war, began a systematic program of rearmament. Moreover, Kruger's prestige was increased not only among his own people but also among the Cape Dutch and the Free Staters, and in 1897 he formed an alliance with the Orange Free State.

Relations between Britain and the South African Republic steadily deteriorated after the raid. Sir Alfred (later Viscount) Milner, who was appointed high commissioner in 1897, was determined to uphold British supremacy in South Africa and was prepared to "work up a crisis" by demanding the franchise and other civic rights for the *uitlanders*. Kruger, on the other hand, regarded firmness on the franchise question as essential for the maintenance of Boer independence. At the Bloemfontein Conference (June 1899) both the high commissioner and Kruger adopted an attitude of intransigence, and the negotiations broke down over the question of the *uitlander* franchise. Thereafter Chamberlain openly adopted the *uitlanders'* cause; for him, too, it was part of the more important issue of British paramountcy. In August, J. C. Smuts, the state attorney of the South African Republic, offered a franchise for the *uitlanders* after five years' residence, but Chamberlain rejected the conditions attached, which included abandonment of the British claim to suzerainty over the republic. Both sides then drifted rapidly into war. On Sept. 22 the British government drew up a drastic program of demands and decided to mobilize an army corps. Mobilization also proceeded both in the South African Republic and in the Orange Free State, which, although having endeavoured throughout to avert war, had resolved to support its ally. On Oct. 9 the republics presented an ultimatum, demanding the withdrawal of British troops from the frontiers, which only narrowly forestalled the British ultimatum.

THE COURSE OF THE WAR

On the expiry of the Boer ultimatum (Oct. 11, 1899) there were only 27,000 British troops in South Africa, while the republics had about 48,000 men under arms. The British Army Corps that was later dispatched to South Africa included highly trained field artillery and cavalry, as well as some mounted infantry, which were at that time unique in Europe. But it was hampered by incompetence in the high command and by the difficulty of the terrain—vast expanses of open country with poor communications. The Boers had an initial advantage in their mobility and their experience of the country. They were mounted riflemen, loosely organized in district commandos (*see* Commando) under elected officers, each army being supported by a small corps of state artillery. But in the early stages of the war the lack of discipline and the weakness in the command of the Boer forces offset these advantages.

The war can be divided into two stages. The first was the period

of regular warfare, which ended with the annexation of the Transvaal in September 1900; the second was the period of prolonged skirmishing, which continued until May 1902, when peace was signed.

The war opened with the investment of Mafeking by a Transvaal force under Gen. P. A. Cronje and the envelopment of Kimberley by Free State commandos under C. J. Wessels (October 1899). Meanwhile, a large Boer army under Gen. P. J. Joubert, commander of the Transvaal forces, had invaded the northern triangle of Natal, where Lieut. Gen. Sir George White was commander in chief of 16,000 British forces, most of which were divided between Ladysmith and Dundee. The Boers advanced on these centres from the north, east, and west. Although one Boer force under Lukas Meyer was repulsed at Talana Hill, outside Dundee, on Oct. 20, and another under Gen. J. H. M. Kock was defeated at Elandslaagte on the following day, the Boers forced the British to fall back on Ladysmith. White's attempt to break the Boer lines resulted in the Battle of Ladysmith (Oct. 30), in which the British losses totaled more than 1,200 (69 killed, 249 wounded, 954 missing) against the Boers' 200. Thereupon the Boers started the long siege of Ladysmith and seemed about to overrun the whole of Natal.

Buller's Offensive.—Gen. Sir Redvers Buller, who had been appointed to the supreme command in South Africa, arrived in Cape Town (Oct. 31, 1899) followed by his army corps. The situation with which he had to deal was serious. On Nov. 1, M. T. Steyn, president of the Orange Free State, sent his commandos into the Cape Colony, where they found support among the colonists, despite the imposition of martial law by the Cape government in the invaded districts. On the western front Mafeking and Kimberley were in a state of siege, and in Natal the British position was critical. Buller split his army corps into three unequal parts. One, under the command of Lord Methuen, was to relieve Kimberley and Mafeking in turn; the second, under the command of Lieut. Gen. Sir William Gatacre, was to contain the commandos invading the Cape Colony; the third, under Buller's own command, was to relieve Ladysmith. But Buller's whole scheme broke down in the series of disasters that the British sustained during "Black Week" in the middle of December. On Dec. 10 Gatacre essayed a night march and attack on the Boer position near Stormberg Junction, but, having been misled by his guides, he was himself surprised and forced to return to Molteno with a total loss of about 700 men. On the following day Methuen, who had succeeded in crossing the Modder River on his march to the relief of Kimberley, was defeated in the Magersfontein Hills, just south of the besieged town, by the forces of the Boer generals J. H. de la Rey and Cronje. The British lost about 1,000 men, including Maj. Gen. A. J. Wauchope. The Boers' victory was largely due to De la Rey's original and effective measure of digging and defending long narrow trenches along the foot of the hills. Then on Dec. 15 Buller was decisively defeated at Colenso, on the Tugela River, by the able Boer general Louis Botha. Botha routed the British forces and lost 29 men against the British loss of 1,139. Buller immediately sent orders to White, who was still besieged in Ladysmith, to destroy his guns and surrender the town. But White refused to do so, and the siege continued.

In England "Black Week" brought a reaction of deep shock. The Cabinet appointed (Dec. 16) Field Marshal Lord Roberts to the supreme command, with Maj. Gen. Lord Kitchener as his chief of staff. Volunteer forces, both mounted and infantry, were raised, and the militia were invited to come forward. The empire—Australia, New Zealand, Canada, and others—contributed contingents (which amounted in the end to a total of 40,000 volunteers), and at the same time the Boer forces were augmented by volunteers from many countries of Europe. In the early days of 1900 the struggle swayed to and fro. On the western front, in the far north Cape, the settlement of Kuruman surrendered (January 1900) to the Boers' besieging force; in the Cape midlands Maj. Gen. John French (later 1st earl of Ypres) was pressing on Colesberg; while in Natal the fate of Ladysmith hung in the balance. On Jan. 6 the Boers made an attempt to overwhelm the besieged town but without success. This was followed by two attempts on the part of Buller to relieve it. In the first of these he was forced to withdraw with very heavy losses in the Battle of Spion Kop (Jan. 24). On Feb. 5 he again crossed the Tugela River but failed through indecision to press the advantage he had attained and was defeated at Vaal Krantz.

Roberts' Advance.—Roberts and Kitchener arrived in Cape Town on Jan. 10. Roberts' plan was to assemble his army on the Modder River in the west and to carry out an eastward march to strike at Bloemfontein, the capital of the Orange Free State. He kept his plan secret and created the impression that he was concentrating his forces in the Cape midlands area, near Colesberg. On Feb. 11 Roberts began his march from between the Modder and Orange rivers. He sent French from Ramdam (near Graspan) on a flanking movement northeast toward Kimberley, where Rhodes's vociferous demands and the serious health situation in the town, whose populace was near starvation, created an urgent need of relief. Sweeping round Cronje's main force in the Magersfontein Hills, French put an end to the siege of Kimberley on Feb. 15. Thereupon Cronje abandoned his Magersfontein defenses and escaped eastward through the British lines, which were also moving east. But, hampered by his long train of wagons, he was surrounded at Paardeberg (Perdeberg), southeast of Kimberley, and after a long and stubborn resistance was forced to surrender to Roberts with about 4,000 men on Feb. 27. The next day Buller in Natal at last succeeded in forcing the Tugela defense line and relieved Ladysmith, which by this time was in a desperate state. The Boers' besieging force retreated in disorder. The turning point in the first stage of the war had been reached. Kimberley and Ladysmith had been relieved, the Boer Army in the west had been captured almost entire, that in Natal was retreating in confusion, and in the Cape the invaders De la Rey and H. Schoeman had been forced to flee to Bloemfontein. On March 5 Presidents Kruger and Steyn offered peace proposals to the British government on the basis of continued independence for the republics, but after the fall of Bloemfontein these were rejected by the British prime minister, the marquess of Salisbury.

Capture of Bloemfontein.—Roberts, meeting with little resistance from the Boers, continued his advance on Bloemfontein, which he entered and occupied on March 13. He considered that the war in the Free State was over and on March 15 issued a proclamation allowing those burghers who laid down their arms to return to their homes. But the Boers gained a valuable breathing space by the delay of Roberts' army in Bloemfontein, where an outbreak of enteric fever took a heavy toll of lives. At the same time the death of Joubert (March 27) brought the more vigorous Louis Botha into command of the Transvaal forces. Further strengthened by a decision to reduce all transport to a minimum and to impose stricter discipline on their forces, the Boer leaders again took the initiative. Christiaan de Wet captured the waterworks at Sannah's Post outside Bloemfontein after inflicting a defeat on Gen. R. G. Broadwood (March 31) and followed this up by securing the surrender of a British detachment near Dewetsdorp, 40 mi. SE of Bloemfontein, on April 4.

Relief of Mafeking.—Early in May, Roberts set out from Bloemfontein on his march to the Boer capital of Pretoria. On May 17 a flying column, from near Kimberley, relieved Mafeking, where Col R. Baden-Powell had maintained morale in increasingly difficult circumstances. Roberts, having reached the Vaal River and announced the annexation of the Orange Free State as the Orange River Colony (May 24), continued his successful advance, invaded the Transvaal, and on May 31 entered Johannesburg. With practically no resistance he was able on June 5 to occupy Pretoria, from which Kruger had already fled east along the Delagoa Bay railway line to Middelburg. The occupation of Pretoria was secured by Roberts' displacement of Botha's force at Diamond Hill (June 11–12), east of the capital. But the end of hostilities was not yet in sight. As Roberts concentrated on his eastward offensive against Botha, his rear was threatened by De la Rey, who harried the British forces in the western Transvaal. At the same time De Wet was engaged in disrupting railway communications in the Orange Free State. However, on July 30, a party of more than 4,000 Boers under Marthinus Prinsloo was forced to surren-

der after being trapped in the Brandwater Basin, south of Bethlehem, in the Orange Free State, but De Wet himself had already escaped and made his way northward.

Roberts' main army was joined (Aug. 14) by the forces of Buller, who had marched through northern Natal. On Aug. 27 they defeated the Boer commandos at Bergendal, near Dalmanutha, 45 mi. E of Middelburg, and caused them to disperse. Kruger, who had been fleeing east in advance of the British forces, left the republic (Sept. 11) and entered Portuguese East Africa. On Oct. 19 he set sail for Europe, where it was felt he would be safe and might obtain aid for the Boer cause. S. W. Burger was appointed to act as president in his absence.

The Guerrilla War.—Roberts had already proclaimed the annexation of the Transvaal (Sept. 1). Then, believing that the war was over, he laid down his command in South Africa in favour of Kitchener (November 1900) and in January returned to England. But a new war had already begun, in which the Boers adopted guerrilla tactics. They concentrated on disrupting railway communications, capturing isolated posts, and avoiding contact with the columns sent in pursuit of them. In the Orange Free State, De Wet roused the burghers to the new tactics and raised local commandos. He was unable at the beginning of December 1900 to cross the swollen Orange River and carry out his proposed invasion of the Cape, but two of his generals, P. H. Kritzinger and J. B. M. Hertzog, entered the colony (Dec. 16) and made their way southward, evading the British columns sent in pursuit of them. The new tactics were also adopted in the Transvaal, De la Rey operating in the west and Botha in the east.

Concentration Camps.—Kitchener, on taking over command in November 1900, was faced with the problem of dealing with the new war. Having appealed to Britain for more manpower, he extended the "scorched earth" policy that Roberts had already begun. Boer farms were devastated, and the women and children of the men on commando were interned in concentration camps, where for a time the death rate from disease was very high. From the British point of view Kitchener's internment policy was not a success; it added an extra burden to the fighting forces, and it further stimulated the spirit of the Boers. At the end of January 1901 Kitchener launched two large-scale offensives, the first against De Wet, who on Feb. 10 crossed the Orange River to invade the Cape Colony. But closely pursued by Col. H. C. O. (later Viscount) Plumer, he gave up his attempt and retired (Feb. 28) across the river. A second offensive, under French, was launched (Jan. 28) against Botha in the eastern Transvaal, from where he was planning an invasion of Natal. Botha managed to escape with his forces from Ermelo (Feb. 6), whereupon he was asked by Kitchener to discuss peace terms. A meeting took place at Middelburg on Feb. 28, 1901. Kitchener proposed peace terms, which included a general amnesty for Boers and for Cape and Natal rebels and the grant of self-government to the northern colonies as soon as possible. But, largely because the British government was not in favour of an amnesty for the rebels, the negotiations broke down (March 16).

Blockhouses.—As the Boers continued their skirmishing tactics, Kitchener adopted a policy of building corrugated iron blockhouses along the railway lines. When these proved effective, he extended them away from the railways to form fortification lines across the Free State and later across the Transvaal, so that eventually the whole country was split up into small areas, within which the Boer forces could be localized and overwhelmed by British troops. Meanwhile, he continued his policy of interning women and children and on Aug. 7 issued a proclamation to the effect that all Boers who had not surrendered by Sept. 15 would be punished and the leaders permanently banished from South Africa. But the Boers, who had been exhorted by the exiled President Kruger to continue fighting, were not daunted. Botha made an unsuccessful attempt at invading Natal early in September. On Sept. 3 Smuts invaded the Cape Colony and by the end of October was within 50 mi. of Cape Town. During the next six months Kitchener concentrated his efforts on the three able Boer generals who were still harassing the British forces: Botha in the eastern Transvaal, De la Rey in the western Transvaal, and De Wet in the eastern Free State. The last notable Boer victory was gained by De Wet at Tweefontein, 50 mi. W of Harrismith, on Christmas Day. Thereafter Kitchener brought his blockhouse system to completion and by a series of raids forced Botha to retire from the eastern Transvaal in February 1902. In the same month he launched intensive drives across the Free State, carefully planned to comb the countryside, and in this way he succeeded in rounding up large numbers of De Wet's men. In the western Transvaal, De la Rey's forces were gradually worn down during March, while in the Cape Smuts continued his skirmishing. The Boers' resistance steadily weakened. On April 12 their leaders met Kitchener in Pretoria and agreed to discuss peace proposals.

Treaty of Vereeniging.—On May 15 representatives of the Boer governments and 60 delegates elected by the Boer commandos of the two republics met at Vereeniging to discuss peace. A deputation, consisting of Botha and four other Boer leaders, was chosen to negotiate with Kitchener and Lord Milner, the high commissioner, for limited independence. The British, however, stood firmly by their Middelburg proposals (*see* above). A draft treaty, which consisted essentially of these proposals, was drawn up and, in the form approved by the British government, was submitted to the convention. On May 31, 1902, the treaty was agreed to and signed.

The terms of the treaty were as follows: (1) the burghers to lay down their arms and acknowledge King Edward VII as their lawful sovereign; (2) all prisoners outside South Africa and internees on acknowledging themselves subjects of the king to be repatriated; (3) no burghers who should surrender to be deprived of their personal liberty or property; (4) no proceedings to be taken against burghers for any legitimate acts of war; (5) the Dutch language to be taught in public schools where the parents of the children should desire it, and to be allowed in courts of law when necessary for the better administration of justice; (6) the possession of rifles to be allowed on the taking out of licences; (7) military administration to be succeeded by civil government as soon as possible, and representative institutions leading to self-government to be introduced as soon as circumstances permitted; (8) the question of granting the franchise to "natives" not to be decided until after the introduction of self-government; (9) no special tax to be imposed on landed property to defray the expenses of war; (10) district commissions to be set up to facilitate resettlement. For this purpose the British government would be willing to grant a sum of £3,000,000 and also offer loans on liberal repayment terms.

The war, which had lasted two and a half years, had cost Britain about 22,000 men and the Boers not far short of 6,000, as well as 4,000 women and 16,000 children who had died in the concentration camps. At the end of the war there were almost 26,000 Boers in prison camps and more than 116,000 were confined in concentration camps.

RESULTS OF THE WAR

As a result of the war the two Boer republics ceased to exist, and crown colony rule was established in the Transvaal and in the Orange River Colony. The whole of South Africa was brought under the British crown, and thus the subsequent political union of the former republics with the existing colonies of the Cape and Natal was made possible. The Treaty of Vereeniging contained a promise of self-government for the new colonies, and this was granted to the Transvaal in December 1906 and to the Orange River Colony in June 1907. For both political and economic reasons a movement for the closer union of the four self-governing colonies developed, and this led to the establishment of the Union of South Africa in 1910.

The war had the effect of arousing a new national consciousness among the Afrikaner people throughout South Africa. This gave rise first to a cultural and then to a political revival. In the crown colonies, in opposition to Lord Milner's policy of anglicization, a "Christian National Education" movement developed. Private schools were established, and these fostered Afrikaner national sentiment among the rising generation. National consciousness expressed itself also in a language movement. The Taalbond (lan-

guage union), revived in 1903, encouraged the use of High Dutch to combat English. Attempts were also made to promote Afrikaans, the spoken language of the Afrikaner people, as a written language and to obtain official recognition for it. The Afrikaans poetry and prose that the language campaign produced gave rise to a virile national literature. At the same time the Afrikaners in the new colonies were beginning to form political organizations. In the Transvaal the Het Volk ("The People") Party was formed in January 1905, followed in May 1906 in the Orange River Colony by the Orangia Unie ("Orange Union"), both pledged to the ideal of self-government.

For Britain the war brought to an end the period of late-19th-century imperialism. Moreover, it revealed to Britain many defects in its military organization and taught it tactical lessons, such as the importance of accurate rifle fire and of taking cover, which were to prove valuable in World War I.

SOUTH AMERICA, the fourth largest of the continents, is located between longitudes 34° and 82° W and latitudes 13° N and 55° S. It has an approximate area of 6,879,000 sq.mi., about 13% of the land surface of the earth. Its estimated population (1963–64) was 160,000,000, equal to approximately 23 persons per sq.mi. The continent, with adjacent islands, is made up of 11 sovereign republics—Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Guyana (until 1966 the colony of British Guiana), Paraguay, Peru, Uruguay, Venezuela—and 2 European colonies—French Guiana, and Surinam, or Dutch Guiana. South America is joined to Central America by the Isthmus of Panama.

Geographically, the continent is dominated by the Andes Mountain chain, which extends in a generally north-south direction for 4,500 mi. The Magdalena (Colombia), Orinoco (Venezuela), São Francisco (Brazil), and Río de la Plata (Argentina, Brazil, Paraguay, and Uruguay) are major river systems, but each is dwarfed by the Amazon, the largest river in the world in terms of area drained and volume of flow. The barren, saline Atacama Desert of the west coast stands in marked contrast with the tropical jungles of Bolivia, Brazil, Ecuador, Peru, and the Guianas on the one hand and temperate Valdivia, Chile, with an average annual rainfall in excess of 100 in., on the other.

This article is organized into sections as described in the following outline:

I. PHYSICAL GEOGRAPHY

A. Geology

The most ancient core areas of South America lie in the Brazilian Shield and the Guiana Highlands. Analogous to the Laurentian Shield of North America, they consist largely of a basement complex of pre-Cambrian gneisses and schists, exposed in some areas and overlain in others by sedimentaries mostly of Paleozoic Age. Many of the older formations have their counterparts in age, composition, and attitude in southern and western Africa, and the belief is widely held, although not universally accepted, that the two continents were joined until Jurassic time. Much of the rest of the South American continent must ultimately owe its existence to deposition in marginal seas of the products of erosion from the core areas. Extensive and repeated periods of uplift and subsidence brought about major transgressions and retreats of the sea over these marginal areas, with consequent deposition of massive beds of marine sediments and a gradual increase in the size of the continent.

A vast geosyncline on the western and northern margins of the continent became the repository in the Mesozoic Era of accumulations of sediments many thousands of feet thick. In the Upper Cretaceous the great weight of these deposits gave rise to crustal instability with crumpling and uplift of the strata, a process that continued throughout the Tertiary and resulted in the formation of the Andes. Intrusions of magma accompanied this activity, and volcanism was widespread. Volcanic activity is still a feature of the Andes, although it has entirely ceased in such older lands to the east as the Paraná Basin of southern Brazil and Paraguay, where successive and widespread outflows of basaltic lava engulfed the land in the Jurassic period.

Extensive glaciation has occurred in South America in at least two distinct geologic epochs, the Carboniferous and the Pleistocene. In the former case the main centre appears to have been in southern Brazil; in the latter, in the southern Andes. A few small relics of a formerly extensive continental ice sheet still survive in southern Patagonia.

B. Physiography

1. The Coasts.—The South American continent rises abruptly from the ocean floor along much of its coast, but the steepness of the continental margin is more marked on the western side than on the eastern. The west coast between latitudes 5° and 35° S displays little development of a continental shelf and drops off sharply to a series of deep submarine trenches parallel to the shore. In the neighbourhood of 26° S the Richards Deep exceeds 25,000 ft. in depth within 50 mi. of the coast. In general, the Pacific coast north of the Patagonian archipelago is but little articulated and is completely lacking in good natural harbours.

From 41° S to Cape Horn the Pacific coastal zone is a series of islands, channels, and fjords, results of subsidence and glaciation. North of 41° S the land between the Andes and the sea averages 40–50 mi. in width. In southern and central Chile a longitudinal interior valley is bordered on the west by a coast range whose elevation increases toward the north. Northern Chile has a high cliff coast situated in front of a series of interior basins. In Peru, Ecuador, and Colombia the coast range is largely absent.

The east coast is in strong contrast with the west. Between Cape São Roque and Rio Grande do Sul the coast generally follows the sinuous eastern edge of the Brazilian Plateau. Along this coast lie some of the world's most beautiful harbours, notably those of Recife, Salvador, Vitória, Rio de Janeiro, and Florianópolis. Farther south the estuary of the Río de la Plata is the most marked indentation of the entire South American coast. It is the outlet for the combined waters of the Paraná and Uruguay river systems. The Patagonian coast is poorly endowed with natural harbours. Although many embayments occur, their utility is reduced by shallow water, high tidal ranges, and coastal cliffs.

The east coast of South America has few islands, and these, except Trinidad, off the coast of Venezuela, and Marajó, at the mouth of the Amazon, are mostly small. Trinidad (area 1,980 sq.mi.) is separated from the continent by the Gulf of Paria. Along the island's northern edge is a range of mountains with a

Lake Maracaibo, Venezuela, centre of the petroleum industry of Latin America. The lake receives the drainage of the slopes of the eastern cordillera of the Andes Mountains. Although it is called a lake, it is, in fact, a 133-mi.-long bay of the Gulf of Venezuela

Magdalena River, Colombia. A major commercial artery for several centuries, the Magdalena drains the central and eastern slopes of the Colombian Andes and empties into the Caribbean near Barranquilla

Plains near Esmeralda, Venezuela, part of the Orinoco watershed which lies between the northern Andes and the Guiana Highlands (in background)

FIG 1.—COUNTRIES AND MAJOR CITIES AND SURFACE FEATURES OF SOUTH AMERICA

mainland of Peru, the Galápagos Islands on the Equator, and the islands of the Guayas River delta near Guayaquil.

2. Landforms.—The continent of South America is composed of the following major surface forms: the cordilleras of the Andes in the west and north; the Guiana, Brazilian, and Patagonian uplands in the east and south; and the lowlands that divide the highlands from one another, namely, from north to south, the Orinoco depression, the Amazon Basin, the Paraguay Basin, and the pampas.

The Andes, one of the greatest mountain systems in the world, are more than 4,500 mi. long and are exceeded in average height only by the Himalayas. The southern Andes are a single chain, but north of latitude 28° S they form a complex system. Widening to a broad plateau in Bolivia, they narrow to a series of parallel ranges in Peru, continue in two parallel ranges in Ecuador, and then fan out in Colombia into three distinct ranges, two of which end near the Caribbean shore while the easternmost continues through northern Venezuela into Trinidad. Volcanic cones are present in three separate areas (for further details, *see* ANDES).

The Guiana Highlands and the Brazilian Shield together represent the ancient core area of the South American continent, divided into two unequal sections by the Amazon geosyncline. Waterfalls and rapids occur along all the streams passing over the edge of these uplands. Angel Fall in the Guiana Highlands is the highest uninterrupted waterfall in the world (3,212 ft.). The Paulo Afonso Falls on the São Francisco River in northeastern Brazil were harnessed in the late 1940s for a major hydroelectric installation. Crystalline rocks, in the areas of high rainfall, weather into characteristic dome-like shapes, as exemplified by the celebrated Sugar Loaf overlooking the bay at Rio de Janeiro. The highest point in the Guiana Highlands is Mt. Roraima (9,094 ft.), and on the Brazilian Shield, Pico da Bandeira (9,495 ft.). Patagonia is mostly a succession of arid plateaus, characterized by horizontal beds of sandstone and widespread lava caps.

In South America the development of lowlands is far greater in the interior of the continent than near the periphery. Only on the Atlantic coast, around the mouth of the Amazon and near the Río de la Plata, do extensive lowlands occur next to the sea. Typically, the lowland areas are pouch shaped, with their greatest width inland. The Llanos del Orinoco occupy a structural depression between the northern Andes and the Guiana Highlands. The Orinoco River does not flow along the central axis of the llanos but at the base of the Guiana Highlands, in part a consequence of the great deposition of alluvium by tributary streams issuing from

maximum height of 3,085 ft., which is geologically a continuation of the Cumaná Range of Venezuela. On the south side of this island is the famous asphalt lake—the largest known deposit of its kind. West and north of Trinidad and lying farther off the coast are several small islands of historical interest and considerable commercial importance: Tobago, Margarita, Tortuga, and the Curaçao group. The main island of the Fernando de Noronha group of volcanic islands, 230 mi. off Cape São Roque, has an area of only 7 sq.mi. Although separated from the mainland by a channel 13,000 ft. deep, it really stands upon the submerged corner of the continent. The Falkland Islands in latitude 51° S also stand upon the submerged edge of the continent. Their fauna and flora indicate that they were once a part of the mainland, from which they are now separated by shallow water. On the west coast north of the Patagonian archipelago are the Juan Fernández Islands west of Valparaíso, the famous guano islands close to the

the rapidly eroding Andes. The Amazon Basin has an exceedingly low gradient, Manaus, 800 air miles from the Atlantic, being only 130 ft. above sea level, and Iquitos, 1,700 air miles inland, only 350 ft. In spite of this low gradient, far less of the Amazon lowland is subject to inundation than is commonly supposed, the great bulk of the land lying above the level of highest floodwater on the major streams. In its widest section the upper Amazon Basin affords access over low divides (about 1,000 ft. elevation) into the Orinoco depression to the north and the Paraguay Basin to the south. The Paraguay-Paraná geosyncline begins in the north with the great region of swamp (Pantanais grandes) in western Mato Grosso and with the Gran Chaco of Bolivia, Paraguay, and Argentina. Slopes are so gentle that drainage is slow and imperfect. Toward the south the Chaco grades into the pampas, while the swamps of Mato Grosso find their general counterpart in the adjoining Mesopotamia section of Argentina.

3. Drainage.—The most important river systems of South America—the Amazon, Orinoco, and the Paraná-Río de la Plata—have the greater part of their drainage basins in the lowland belt. The chief headwater tributaries of the Amazon and the Orinoco have their sources in the Andean Highlands, where they have cut deep valleys. The principal sources of the Paraná-Río de la Plata system are in the Brazilian Plateau. These three river systems together drain an area of about 3,700,000 sq.mi. The Amazon is the largest river in the world, though not the longest. At the narrows of Óbidos, where it is constricted by spurs of highland projecting from north and south, it has a width of $1\frac{1}{4}$ mi., a depth of 270 ft., and an average current of 2.7 mph. During flood stages it rises about 25 ft., and the current in the narrows increases to 4.2 mph. The main stream is navigable for ocean steamers as far as Iquitos, about 2,300 mi. from the sea. In time of high water the main stream of the Orinoco is navigable for 1,000 mi. or more.

Other important rivers are the Magdalena in Colombia, the Essequibo in Guyana, and the São Francisco in eastern Brazil. The Magdalena is navigable in two sections separated by the rapids at Honda for river steamers as far as Girardot, the river port of Bogotá. The São Francisco, which rises in the highlands of Minas Gerais, is navigable nearly to the falls of Paulo Afonso, 140 mi. from its mouth, and for 850 mi. above the falls.

Most of the lakes of South America are mountain lakes in the Andes or along their base. Of the Andean lakes, Titicaca (*q.v.*) and Poopó are the largest. The glacial lakes along the eastern base of the Andes in southern Argentina and those of the Llanquihue District of southern Chile are described in the articles ANDES, ARGENTINA, CHILE, and PATAGONIA. Along the east coast there are occasional lakes of brackish water, such as the Lagoa dos Patos of southern Brazil, produced by depression of the coast and the closing of the mouths of estuaries formed thereby or by barrier beaches thrown up by the sea. Lake Maracaibo in northern Venezuela is a large, narrow-necked bay of the Caribbean rather than a true lake, but its waters are brackish.

C. CLIMATE

South America, the only southern continent to extend far into temperate latitudes, tapers toward the South Pole and hence does not experience the extremes of temperature of the northern continents. The winters in temperate latitudes are warmer and the summers cooler than in North America or Asia. The continent is broadest in the equatorial section and has larger areas of hot tropical lowlands than any other continent.

Average annual temperatures in the Amazon Basin are about 80° F. (27° C.), and seasonal variations are slight. Quito, near the Equator but at an elevation of 9,350 ft., averages about 55° F. (13° C.) in every month. Seasonal temperature ranges increase with latitude and reach their maximum in northwestern Patagonia, where July averages 32° F. colder than January. Winter freezing at low elevations is common in Tierra del Fuego and Patagonia, is by no means rare on the Argentine pampas or in south-central Chile, and occurs in southern Brazil at elevations above 1,000–2,000 ft.

The northward-flowing Humboldt (Peru) Current and associated upwelling water keep temperatures on the Pacific coast cool

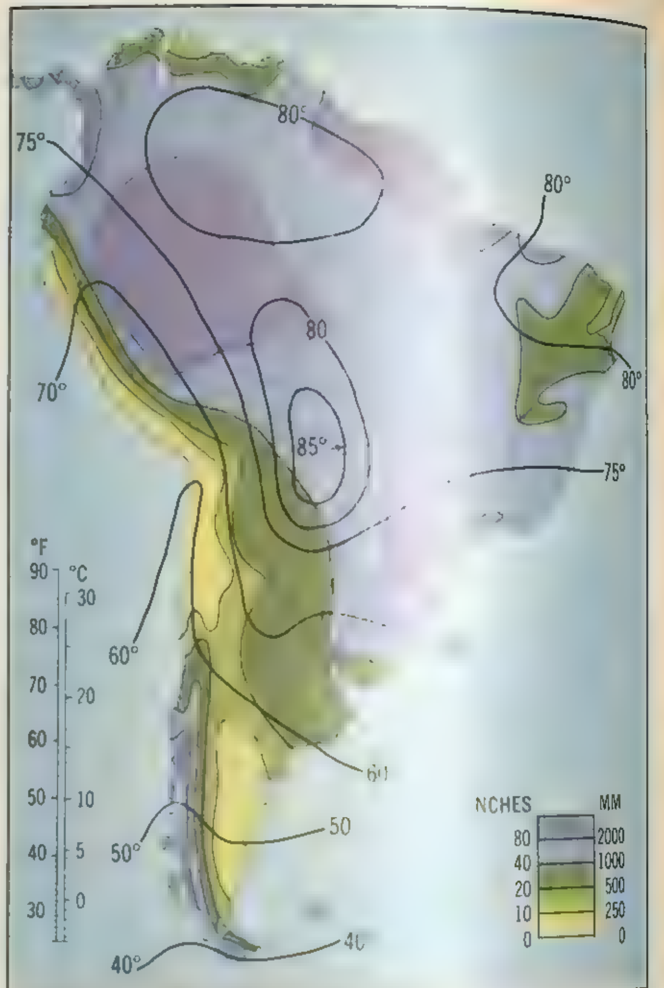

FIG. 2.—AVERAGE ANNUAL RAINFALL AND TEMPERATURE (IN °F)OF SOUTH AMERICA

as far north as the Equator. The coast of Argentina is cooled by the Falkland Current. Elsewhere around the continent warm water washes the shores: the South Atlantic equatorial current flowing west encounters the bulge of Brazil and divides into the south-flowing Brazil Current and a coastal current that flows northwest into the Caribbean; on the northern Pacific coast the equatorial countercurrent sends a warm-water eddy to wash the shores of western Colombia and Ecuador.

The rainfall pattern of the continent is closely connected with the distribution of winds and air masses. Most of tropical South America east of the Andes has prevailing winds from the northeast, east, or southeast. They transport moisture from the warm Atlantic Ocean and give copious rainfall by convection. Rainfall totals average 90–120 in. per year along the lower Amazon and the coast of the Guianas. The middle Amazon Basin has somewhat less rain (60–70 in.), and the upper basin has more than 90 in., possibly exceeding 150 in. in exposed portions of the Andean foothills. The interior of the Brazilian bulge is generally dry and periodically subject to extreme drought. The Llanos del Orinoco and the Guiana Highlands have moderate to high rainfall, with a strong maximum in summer. Much of northwestern South America has two rainfall maxima associated with the two periods of high sun. The Pacific shores of Colombia and northern Ecuador are extremely rainy, while the Gulf of Guayaquil marks the transition to the dry west-coast conditions of Peru and northern Chile. The Atacama Desert along this part of the coast is one of the driest areas in the world. South of 33° S rainfall is adequate west of the Andes, and south of 38° S it becomes excessive. Cyclonic precipitation is characteristic of middle and southern Chile, associated with the westward movement of storms from the Pacific. Valdivia (latitude 40° S) averages 105 in. of rain per year, and the fjorded coast farther south receives even more. Argentine Patagonia lies

in the rain shadow of the Andes and is mostly steppe and desert. The grasslands of Argentina, Uruguay, and southern Brazil have moderate rainfall (25–50 in.) well distributed throughout the year. Eastern Paraguay is moist (50–75 in.), while the Chaco is moderate to dry and has a dry winter.

D. Vegetation

The pattern of vegetation for the continent is complex, especially in the highlands and in areas of critical rainfall differences. The actual vegetation cover deviates most from the natural forms in areas of dense human settlement and in regions where the land has been converted into permanent farms or artificial pasture. A question still remains as to how much influence the pre-Columbian Indian exerted on the natural vegetation cover. It is possible that the greater extent of tropical grassland north of the Amazon lowland and in the northern fringes of it as compared with areas south of the Amazon is in part a reflection of greater aboriginal population density in the northern areas and of a greater use of fire for making clearings and driving game. The comparable areas south of the Amazon have a cover of semideciduous woodland that has been much less affected by fire.

The largest more or less uniform vegetation region is that of the tropical lowland rain forest in the Amazon Basin and the Guianas, with an outlier along the east-central Brazilian coast. It is the largest area of its kind in the world and has several distinct subtypes. The number of plant species growing together in this forest is greater than in any other plant association in South America. Additional characteristics are dense growth, generally slender trees, storied vegetation, lianas, parasites, and epiphytes, and, at times, buttressed trunks.

A semideciduous phase of the tropical forest is found in the Venezuelan part of the Guiana Highlands and in some inland sections of central and southern Brazil. It is somewhat less luxuriant than the true lowland rain forest, and some of the plants that compose it drop their leaves seasonally because of dryness or low temperatures. Tropical highland forest, in part cloud forest, is found on the eastern flanks of the Andes from latitude 20° S northward. Mangrove forests fringe most of the warm-water coasts of the continent from the Gulf of Guayaquil clockwise almost to Rio de Janeiro. A palm forest, also tropical, is characteristic of a portion of the state of Maranhão.

Temperate or mid-latitude forests are of two main types: the araucaria evergreen forest of southern Brazil and the more extensive deciduous forests with small araucaria enclaves in southern Chile. In southern Brazil the araucaria, a coniferous softwood, is the basis of a significant lumber and paper industry.

One step below the forests in magnitude are the woodlands of the continent, composed chiefly of lower trees, more widely spaced, with an admixture of shrubs and grass. As compared with the forests, they are found in areas of less total and less uniform rainfall. Semideciduous woodlands known as *campos cerrados* are characteristic of central Brazil. Especially thorny woods are found in northeastern Brazil, in much of the Chaco, and in northernmost Colombia and Venezuela. Park landscapes occur along the Paraguay River and in the hill lands west of the Chaco. They are dotted with well-spaced trees, the intervening areas being covered with grass and shrubs, and represent a most attractive plant association.

Shrub lands display a further diminution in scale, and the typical plants are bushy rather than treelike. They are characteristic of generally dry areas and of those with pronounced seasonal drought. Various forms are found in the Andean foothills behind the tropical coastal desert of Peru, in central Chile, in the lands west of the Argentine pampas, and in eastern Patagonia.

Tropical grasslands are characteristic of the llanos, of the coastal fringe of the Guianas behind the mangrove forest, of parts of the Guiana Highlands in northernmost Brazil, and of certain sections of the Amazon, including the northern and interior parts of Marajó Island. South of the Amazon forest, tropical grasslands are rare, but two large areas of palm-savanna swampland are found.

Temperate grasslands are characteristic of the pampas of Argentina and of adjacent areas in Uruguay and southernmost Brazil. At intermediate elevations they occur near the araucaria forests of southern Brazil, as well as in the Peruvian Andes. At high Andean levels moist alpine grassland is found in equatorial and mid-latitude areas, whereas a dry phase (*puna*) covers most of the intervening section in the Peruvian and Bolivian altiplanos and in parts of northern Chile and Argentina. Extreme aridity in the Atacama Desert of coastal Peru and northern Chile causes an almost complete absence of vegetation.

FIG. 3.—MAJOR VEGETATIONAL ZONES OF SOUTH AMERICA

E. Animal Life

The native animals of South America belong largely to the so-called neotropic realm of animal geography. For obvious reasons there is a fair correspondence between the occurrence of specific animals and the distribution of native vegetation.

The tropical forests contain a fauna characterized by several kinds of monkeys, the tapir, rodents (including the capybara, the largest rodent in the world), birds (parrots, egrets, hummingbirds, etc.), and reptiles (especially crocodiles). Large members of the cat family are relatively rare, as are the large herbivores. The insect world is represented in great numbers. A most characteristic, though not common, member of the Amazonian fauna is the manatee, a vegetarian, aquatic mammal. Just as characteris-

tic, and unfortunately all too common, is the piranha, a small, fierce freshwater fish that attacks other animals that venture into its waters. A school of piranhas has been known to kill a cow and to consume it completely, except for the skeleton, in less than five minutes.

The greatest contrast to this tropical lowland development of animal life is found in the high Andes and in the cold steppes and deserts of Patagonia. Among the important animals native to the central Andes are the four members of the American branch of the camel family: the guanaco, llama, alpaca, and vicuña. The guanaco and vicuña have not been domesticated, whereas the llama and alpaca are found only in the care of man. The llama is the common beast of burden of the Andean Highland Indian, the alpaca is a prolific bearer of fine wool, and the vicuña has a fleece of unbelievable softness and thickness. A rodent found in parts of the high Andes and famous for its magnificent fur is the chinchilla.

The guanaco ranges beyond the Andes into Patagonia and at one time was fairly common on the Argentine pampas. Even wider in range is the rhea, the three-toed South American ostrich, which extends from Tierra del Fuego into central Brazil.

The shrub lands and woodlands south of the Amazon have a fauna that well expresses their transitional character between the Amazon on the one hand and the Chaco and pampas on the other. Truly tropical forms occur there, such as monkeys, anteaters, sloths, tapirs, and parrots, but animals from the colder south are also found, including the rhea, the armadillo, and the raccoon. Large members of the cat family, including jaguars, leopards, and pumas, occur in the Brazilian state of Mato Grosso and other inland areas. Some of these animals are called *tigres* by the South Americans, but true tigers in the wild state are confined to the Eastern Hemisphere.

II. NATURAL RESOURCES

1. Water.—Because of diverse topography and rainfall conditions, the water resources of the continent vary enormously in different areas. In the Andes, navigation possibilities are slight except on the Magdalena River, Lake Titicaca, and the Chilean-Argentine lakes in the south. Irrigation for agriculture is of importance from northwestern Peru to Patagonia. Less than 10% of the Andes' estimated hydroelectric power potential had been harnessed by the mid-1960s.

The Brazilian Shield has better hydroelectric possibilities than the Andes because of the large size of many rivers, the harder rocks, and the occurrence of cliff margins. The harnessing of the Paulo Afonso Falls provides electricity for a large part of northeastern Brazil. Waters impounded near São Paulo are made to fall over the Serra do Mar to provide cheap power and a reliable municipal water supply.

The Amazon River system has more than 8,000 mi. of navigable waterways but presents few possibilities for power development because of the gentle slopes throughout the region.

2. Soils.—Thousands of square miles of dark prairie soil of aeolian and alluvial origin occur in the pampas of Argentina and Uruguay. They are among the best farming soils in the world. Smaller, disconnected areas of good soils are located in various Andean and west-coast valleys, notably in the Valle Longitudinal of Chile, the Guayas lowland of Ecuador and the Cauca Valley of Colombia.

The Paraná Basin is deeply covered with a rich, purplish-red soil called *terra roxa*, derived by weathering from basaltic outflows. This soil is especially suited to coffee growing, as is the volcanic soil of the Colombian Andes.

In the Amazon Basin the soils are generally poor. Small areas of bottomlands have fertile soils, but these are subject to flooding. Infertility and high acidity make most tropical lowland soils submarginal for agriculture. To improve them with lime and fertilizer is rarely feasible.

FIG. 4.—LAND USE AND MAJOR FUEL AND MINERAL AREAS OF SOUTH AMERICA

3. Minerals.—South America is well endowed with petroleum. Roughly one-fourth of the area contains sedimentary basins that might, other conditions being favourable, permit the occurrence of oil-bearing strata. As of 1965 only minor strikes had been made at distances greater than 300 mi. from the Andes, most of the operating oil fields being located in structural basins flanked by Andean ranges, especially in the vicinity of the Caribbean.

Venezuela, with 17,000,000,000 bbl. of proved reserves as of the end of 1963, had by far the greatest wealth of petroleum in South America. It ranked second in the Western Hemisphere and seventh in the world, being exceeded in addition to the U.S. by four countries in the Middle East and by the Soviet Union. Other South American countries with large amounts of proved petroleum reserves include Argentina, Colombia, Peru, and Bolivia.

Natural gas is commonly associated with petroleum, but its commercial utilization has been limited by the remoteness of fields from major population centres. Gas is beginning to be used com-

mercially in Venezuela, but its greatest use occurs in Argentina, where a 1,000-mi. pipeline extends northward from the Comodoro Rivadavia field in Patagonia to supply greater Buenos Aires.

The dearth of good coal in South America represents one of the greatest resource contrasts between the two American continents. Although scattered deposits are found in many parts of the Andes, as well as in southern Brazil, only three countries, Colombia, Chile, and Brazil, have a modest production. Brazil's coal is excessively high in ash content and must be mixed with higher-grade imported coal before it can be utilized industrially. The paucity of coal is a serious disadvantage to the growth of heavy industry on the continent, notwithstanding the plentiful supply of iron ore.

South America is extraordinarily well endowed with deposits of iron ore. The deposits are associated mainly with the ancient core areas of the Guiana Highlands and the Brazilian Shield. Very extensive, high-grade ore bodies have been discovered at or immediately below the surface, and they can be mined directly and cheaply in open pits through the use of power shovels of large size. As a result of the investment in Venezuela of hundreds of millions of dollars by United States corporations, the production of iron ore in that country increased from 2,500,000 tons in 1953 to 12,500,000 tons in 1960, followed by a sizable decline in the early 1960s because of political unrest in the producing area. The main iron districts lie near the Caroní River, a southern tributary of the Orinoco, and their economic development has been greatly facilitated by the availability of cheap water transport.

In Brazil the situation is less favourable, the large ore bodies lying mostly in the interior of the state of Minas Gerais, far from navigable waterways. Although the deposits are rich and more extensive than those in Venezuela, large-scale utilization awaits the improvement of land transport and coastal docking facilities.

Copper occurs mainly in the geologically young lands of the central Andes, in Chile and Peru. Only the great copper mines of North America and central Africa have greater world significance than those of Chile. Commercial tin ores in the Western Hemisphere are confined mainly to Bolivia. The mines are located in the high Andes, some of them being earlier silver mines that were converted to tin mining when the richer silver ores were exhausted. Total tin resources in the Bolivian Andes are estimated to rank third in the world, following southeast Asia and equatorial Africa.

Brazil ranks high in manganese reserves, one of the world's great deposits being located in southwestern Mato Grosso. A smaller but more easily accessible deposit in Amapá lies immediately north of the mouth of the Amazon. Brazil ranks with the Soviet Union and India as a leading producer of manganese.

Other significant minerals in South America are bauxite (aluminum ore), which is especially plentiful in the Guianas and adjacent parts of Brazil; platinum, in Colombia; silver, in Peru and Bolivia; and nitrate, in Chile.

4. Land Use.—Most South Americans live within a few hundred miles of the coasts, and most regions of intensive land use are confined to the same peripheral locations. For the continent as a whole, about 5% of the land is cultivated, whereas about 19% is permanent grazing land and fully 47% is forest. In the early 1960s the proportion of cultivated land by countries varied from a high of 12% for Uruguay to a low of 1% for Paraguay and one-thirtieth of 1% for French Guiana.

Regions of commercial agriculture are widely scattered. The irrigated coastal valleys of Peru are noted for their long-staple cotton, and the Guayas lowland of Ecuador has become the world's leading area of banana production for export. In Brazil more than 2,500,000 ac. are devoted to sugarcane, mainly along the south-central coast and in nearby interior valleys, and tobacco, bananas, and cacao occupy other low-lying districts not far from the sea. The world's greatest coffee-growing district is located on the upland *terra roxa* soils of the Brazilian states of São Paulo and Paraná. The other major coffee area of South America lies in the Colombian Andes, where higher-quality mild coffees are grown.

Mid-latitude agriculture is dominant in the southern part of the continent. The greatest agricultural region of South America is the pampas of Argentina and Uruguay. Wheat is the chief crop, but corn and flax are also significant exports.

Notwithstanding the importance of South America's trade in agricultural commodities or its significance as a source of foreign exchange for the South American countries, it must be emphasized that the vast bulk of the continent's agriculture is devoted to supplying local needs. For subsistence and local commercial markets corn (maize) is grown over much of the continent and leads in total acreage planted. In the tropical lowlands cassava (manioc) and sweet potatoes are widely planted for local consumption, and in the Andes potatoes and other cold-country root and tuber crops are cultivated. Rice and wheat have long been staple food crops and are widely grown wherever conditions are favourable.

Pastoral industries with emphasis on cattle are dominant on the Argentine pampas and adjacent grasslands of Uruguay and southern Brazil, as well as on the llanos of Colombia and Venezuela. Sheep raising for wool is commercially significant in Uruguay, Patagonia, and Tierra del Fuego.

Forest industries based on planted eucalyptus and native araucaria have been organized in southern Brazil; south-central Chile appears to have possibilities of similar development.

Extensive manufacturing districts are not yet common on the continent. Their greatest development has taken place in the environs of São Paulo and Buenos Aires. Examples of individual industrial centres are numerous, however, and include such settlements as Volta Redonda (Brazil), Concepción (Chile), Córdoba (Argentina), Medellín (Colombia), and San Félix (Venezuela).

The great Amazon Basin, the largest undifferentiated region on the continent, is still mainly restricted to a collecting economy, with emphasis on Brazil nuts. (H. J. BN.)

III. ANTHROPOLOGY

Recent archaeological discoveries indicate that man first arrived in South America more than 20,000 years ago. The predominance of large stone projectile points in some Paleo-Indian sites, and of chopping tools in others, suggests that some of the early migrants were primarily hunters, while others specialized in the gathering of wild plant foods.

The introduction of agriculture, which dates from at least 2600 B.C., initiated a relatively rapid cultural evolution that reached different levels in different parts of South America. Some areas remained at the hunting-fishing-gathering level of subsistence. Others adopted agriculture and made certain other cultural advances but continued to live in relatively small and independent communities. Still others developed further, both technologically and socially, and attained the level of chiefdoms. The greatest cultural development of all, which occurred only in the central Andes, was the rise of a full-scale civilization. In the *Handbook of South American Indians*, Julian Steward called these four culture types Marginal, Tropical Forest, Circum-Caribbean, and Andean, respectively, and this usage will be employed below.

1. Racial Type.—The Indians of South America all belong to the Mongoloid racial stock and came originally from Asia by way of North America. The distribution of various morphological characteristics among them has been studied, but as yet no proposed classification of physical types has been generally accepted. The study of blood groups has revealed a high predominance of O, a small amount of A, and practically no B or AB.

2. Linguistic Groups.—The number of language families recognized for South America has varied. A. F. Chamberlain distinguished 83 families in 1913, Paul Rivet 77 in 1924, Cestmir Loukotka 94 in 1935, and J. Alden Mason 91 in 1950. It was generally conceded, however, that more detailed study would decrease the number of independent linguistic groups recognized. In 1956 Joseph Greenberg proposed a tentative classification that reduced the languages of South America to three phyla or superfamilies: Macro-Chibchan (including Chibchan); Andean-Equatorial (including Araucanian, Arawak, Aymara, Chon, Quechua, and Tupí-Guaraní); and Ge-Pano-Carib (including Carib, Ge, Guaycuruan, and Panoan).

3. Marginal Culture.—Societies subsisting entirely or largely on wild food sources were found over large areas of South America in aboriginal times. These groups occupied habitats unsuitable for agriculture. From the Chaco south, it was generally too dry

or too cold for cultivated plants; in eastern Brazil the savanna could not be readily farmed with the tools available. The differences in culture level among Marginal peoples resulted largely from differences in the richness of the wild foods in their respective environments.

The relative importance of hunting, fishing, and gathering varied with the habitat. Among the Tehuelche of Patagonia the hunting of guanacos and rheas provided almost the only source of food. Other tribes, especially those of the Chaco, were more generalized in their subsistence activities and consumed a wide variety of vegetable products along with meat and fish. North of the pampas the principal hunting weapon was the bow and arrow; from the pampas south to Tierra del Fuego it was the bolas (*q.v.*).

Community size was generally small among the Marginal societies. The Yahgan, living in a difficult environment, had local groups of about 15 or 20 persons. On the other hand, after the acquisition of the horse some of the tribes of the Chaco, pampas, and Patagonia had bands of 500 or more. The average size for a Marginal local group was probably about 50. The exploitative nature of their subsistence economy meant that Marginal peoples had to move their campsites periodically to stay abreast of their food supply. With almost no exception, each local group was economically and politically independent. Intertribal gatherings occurred for ceremonial occasions, but they were never permanent. Chieftainship might or might not be hereditary. The chief was usually weak except in societies where achievement in warfare served to increase his power.

Dwellings varied according to the materials available. The guanaco hunters of the south used tents made of animal skins, while the Amazonian Marginals had thatched huts.

Pottery was usually absent, and containers were leather bags, baskets, or gourds. Loom weaving occurred only in the Chaco, where it had diffused from the Andes. Land travel was by foot except among tribes that adopted horse riding from the Spaniards. Watercraft were absent among most Marginal peoples, but a few had bark canoes, rafts, and, in Patagonia, coracles. The band constituted a kinship as well as a local group. Sibs and moieties occurred only among the Ge groups of Brazil, and social classes only among a few horse-riding Indians of the Chaco. Marriage tended to be exogamous, and postmarital residence patrilocal. Matrilocality was found where women's share in subsistence was important, as in the Chaco. There were no specialists except the shaman and the chief, who were nevertheless not exempt from subsistence.

Available evidence indicates that warfare was sporadic and was waged for revenge, witchcraft, and trespass. It rarely involved the capture of prisoners, the taking of land, or the exacting of tribute. The basis of religion was a belief in a number of gods and spirits. Rituals were concerned principally with subsistence and life crises. The shaman was a diviner and curer.

4. Tropical Forest Culture.—The occurrence of Tropical Forest culture coincided closely with the distribution of the tropical rain forest in South America. In the absence of all but the crudest farming tools, the slash-and-burn cultivation characteristic of this culture could be carried on only in areas of loose forest soil. A plot of land was cleared during the dry season, burned just before the rains, and planted with a digging stick. Cultivated plants included corn, sweet potatoes, beans, and peanuts, but the staple crop was cassava. The hydrocyanic acid found in the poisonous variety of this tuber was removed with the help of a number of devices, the best known of which was a sleevelike press called a *tipiti*. Cakes, gruel, and a fermented drink were made from cassava meal.

Fishing was an important supplement to the diet and was carried on with bow and arrow, fish traps, and by drugging with poisonous vines. The hunting of large game was done chiefly with the bow and arrow and with traps; the blowgun, when present, was used mainly against birds and small mammals.

Tropical Forest villages were semipermanent and were located in or near forests and close to watercourses. Houses had a pole framework and were covered with thatch, generally of palm. Usually several families lived in a house, and in some areas the entire village might consist of a single large house. The hammock was used for sleeping by almost all tribes. Community size varied within fairly wide limits. In the Peruvian Montaña, Campa and Amahuaca settlements averaged about 15 persons; along the coast of Brazil, Tupinambá villages often had 600 or 800. The average for the entire area was perhaps 150 to 200. Each village had a chief and occasionally subchiefs or house chiefs. Political authority was not strong except in warlike societies. Chieftainship was sometimes hereditary but was generally only loosely so. Villages were autonomous, and confederacies between them were rare and never permanent.

Baskets were of many kinds and were made by a variety of techniques. Wood carving was common, the most representative item being the one-piece wooden stool. Featherwork was universal and was often beautiful and spectacular. Most tribes had some form of water transport. The dugout canoe was the most typical watercraft, but some tribes had only bark canoes or rafts.

Marriage was generally exogamous, although a number of groups permitted local endogamy. Polygyny occurred, especially for such persons as the chief or shaman. Clans were found among some tribes, such as the Mundurucú and Tucuna, but were not characteristic of the area. The practice of couvade was prevalent. According to this custom, a man took to his hammock or underwent other restrictions at the time his wife gave birth.

Warfare was common to most tribes of the region. Some, like the Mundurucú and the Island Carib, devoted a great deal of time to it. The securing of head trophies and the practice of cannibalism were frequent adjuncts of warfare. Offensive weapons consisted primarily of bows and arrows and clubs. For defense, villages were often palisaded and trails sometimes set with poisoned stakes. Characteristically, warfare was for revenge rather than for economic gain.

Ceremonialism and ritual were well developed. Puberty rites often included tests of courage for the initiates, such as the ant ordeal, whipping, and being bitten by an anaconda. Narcotics of many kinds were used, including tobacco, coca, and *paricá* snuff. Tobacco was particularly important because it was frequently smoked by the shaman in connection with divination and curing.

5. Circum-Caribbean Culture.—Around the Caribbean Sea from Cuba to Nicaragua and in the northern Andes there were societies that resembled Tropical Forest tribes in certain details, *e.g.*, use of the hammock, arm and leg ligatures, and drinking bouts, but were at a distinctly higher cultural level. Agriculture was carried out intensively. The digging stick was still the basic farming tool, but such techniques as planting in mounds and the use of urine fertilizer increased productivity. Irrigation canals and terracing were employed in some places. Corn was the most important crop in the mountain valleys, while cassava was the principal crop in the lowlands. Fruit orchards were also common. Fishing was of importance locally, but hunting was of little significance.

Communities of 2,000 or 3,000 were not uncommon. Towns were generally permanent and well laid out, usually around a large central plaza. For defensive purposes they were often palisaded. Flagstone-paved roads sometimes connected larger towns. Houses were of pole-and-thatch construction rather than of stone. Settlement was often dense: one valley occupied by the Tairona was reported to contain 250 towns. The Anserma had a total population of more than 40,000.

Confederacies and petty states were common in the area. The chief of such political units had considerable authority and prestige. He lived in a special house and was carried about in a litter or on the shoulders of retainers. Some of his many wives and concubines were buried with him after being stupefied with *chicha*, an alcoholic drink made from fermented corn. Society was stratified, with nobles, commoners, and slaves ranking below the chief. Slaves were prisoners of war or persons caught stealing. Commoners could become nobles by valorous exploits in war.

There were craft specialists in pottery making, weaving, goldworking, and stone carving. Metallurgy was particularly well developed. The Quimbaya of Colombia and the inhabitants of Coclé in Panama produced outstanding goldwork. *Tumbago*, an

alloy of gold and copper, was made into utilitarian and luxury goods. Trade was very important, and markets existed. The principal items of exchange were salt, fish, gold, and cotton. Water travel was in dugout canoes along the coasts and on the larger rivers. To cross narrow mountain valleys suspension bridges of vines were constructed. Attire varied considerably. Some tribes went naked or used a simple breechclout. Others wore elaborate cotton mantles or tunics. Class distinctions were reflected in differences in dress.

Marriage was customarily by purchase, and wealthier individuals had several wives. Ceremonies surrounded life crises, especially death. The dead were disposed of in various ways, depending upon locale and social status. Commoners were often cremated and buried in urns; chiefs were interred in stone-lined shaft graves. Funerals were often accompanied by drinking bouts in which huge quantities of *chicha* were consumed.

Warfare prevailed except among a few tribes, such as the Taino. It was waged for conquest of land, to exact tribute, and to capture slaves. Organized military tactics were employed, in some cases directed by special war chiefs. When confederacies fought each other, thousands of warriors might be involved. The favourite weapon was the *macana*, a wooden sword-club, but poisoned arrows and fire arrows were also used. Captured trophy heads were displayed on posts, and the bodies of notable enemies were dried over the fire and stuffed with ashes. Cannibalism was widespread.

The sun and moon were commonly regarded as important deities, and shrines dedicated to them were erected on mountain tops. In trying to influence the supernatural, priests made offerings and sacrifices. Idols, like the *zemis* of the Taino, were used to communicate with the spirit world.

6. Central Andean Culture.—The Inca Empire of the central Andes was the largest and best organized state in aboriginal America. It encompassed about 1,000,000 sq.mi. and had a population conservatively estimated at 6,000,000.

At the base of Inca civilization was a system of intensive agriculture. Cultivated land was extended to the fullest by terracing mountain sides and irrigating deserts. The *taclla*, or foot plow, was used to turn the soil. Llama dung and guano were employed as fertilizer. Able-bodied men farmed plots for the state and the church in addition to their own. Surpluses went into granaries to support priests and other specialists, to maintain the army, and to serve as emergency rations in times of famine. More than 40 different species of crop plants were grown, corn being the most important. In high altitudes, quinoa and potatoes were raised. The principal domestic animal, the llama, served as a beast of burden and as a source of meat, wool, hides, and fertilizer.

The household head, called a *puric*, was allotted a certain portion of land at marriage, which was added to at the birth of each child. The basic unit of settlement was the *ayllu*, an endogamous agricultural community of about 100 families. *Ayllus* were grouped into districts, districts into provinces, and provinces into quarters. The Inca Empire as a whole was called Tawantinsuyu, "four parts of the world." An official governed each administrative unit of the empire. The smaller administrative units were governed by *curacas*, or lower nobility, while the larger units were ruled by members of the higher nobility, called *orejones* ("big ears") by the Spaniards because of the earplugs they wore as symbols of their office. At the top of the hierarchy was the Sapa Inca, or "sole lord." The Sapa Inca was considered the descendant of the sun-god and, thus, divine himself. No one could look directly at the Sapa Inca, and he never drank from the same vessel or wore the same garment twice. He had hundreds of concubines, but his rightful heir was his son by his eldest sister.

There existed a system of forced labour known as the *mita*, by means of which men were drafted for public works. As many as 30,000 men were mobilized at one time to work on roads, fortresses, etc. The *mitimae* system involved forced resettlement and was employed to ease population pressure and to disperse rebellious peoples.

The army, the instrument for expanding the empire, was also recruited by draft. Draftees served either as bearers or as fighting men. On the march the army used the excellent highways and was quartered and provisioned in *tambos*, or fortified storehouses, at points along the road. Military formations and tactics were used during warfare. Soldiers were divided into slingsmen, bowmen, spearmen, etc.

Arts and crafts were practised by full-time specialists and showed great technical excellence. Pottery making, metallurgy, and weaving were especially well developed. Inca architects built solid and imposing structures of dry stone masonry. No system of writing was known, but the *quipu* permitted the keeping of detailed records.

The system of roads consisted of two arterial highways, one along the coast and the other through the highlands. Shorter roads connected the two at various points. Couriers running in relays carried messages or goods rapidly. The 1,400 mi. between Cuzco and Quito could be traveled in five days.

The Inca believed in a creator god, Viracocha, and in a number of other deities, including the sun. The assistance of the gods was invoked at public ceremonies connected with such events as the agricultural cycle and warfare. Many shrines and temples existed throughout the empire. *See* ANDEAN CIVILIZATION; INDIAN, LATIN-AMERICAN. (R. L. C.)

IV. POPULATION

The population of South America was estimated (1963–64) to be 160,000,000. Together with the population of Middle America this gave a total population for Latin America of approximately

FIG. 5.—POPULATION DENSITY OF SOUTH AMERICA

235,000,000, which was about 23,000,000 more than that of Anglo-America. Of the population of South America, almost exactly 50% is in Portuguese-speaking Brazil; Argentina, Colombia, and Peru rank next in order.

The population of South America is arranged in a pattern of more or less separate clusters. In the centre of each cluster there is a central city, of which eight in South America (and ten in Latin America as a whole) had passed 1,000,000 in 1963. Between these clusters there are only scanty populations. A large part of the continent has less than one person per square mile. Most of the clusters are located near a coast, and the vast interior, mostly in Brazil, is one of the world's larger areas of very thin population. Table I shows how this population is divided among the 11 countries and 2 colonies.

TABLE I.—*Area and Population of South America*

Country	Area (in sq.mi.)	Population (1963–64 est.)	Densities per sq.mi.
Total	6,879,122	159,942,730	23.4
Argentina	1,072,067	22,023,431	20.5
Bolivia	424,162	3,653,000	8.6
Brazil	3,286,470	79,937,000	24.3
Chile	292,256	8,369,000	28.6
Colombia	439,512	15,434,090	35.1
Ecuador	105,685	4,877,000	42.2
French Guiana	35,135	35,000	1.0
Guyana	83,000	621,390	7.5
Paraguay	157,047	1,936,000	12.3
Peru	496,222	11,854,000	23.9
Surinam	63,251	320,000	5.1
Uruguay	72,172	2,556,020	35.1
Venezuela	352,143	8,426,799	23.9

The population of Latin America is growing faster than that of any other part of the world. Between 1920 and 1960 the population increased 126.3%, as compared with 92.4% for second-place Australia and New Zealand. Table II shows the medium estimates made by the United Nations for the future population of Latin America by subregions. It is important to note that in all of Latin America the most rapid jump in the rate of increase took place between the pre-World War II period and the period after the war. The decline in the death rate that began generally in the late 1930s is the major cause of this accelerated gain in population. During the 1920s the death rate for 11 Latin American countries for which adequate and comparable data exist was lowered by 6%, but during the short period from 1945 to 1954 the death rate was lowered by 17.1%. With the continued high birth rates in these countries the result was a "population explosion."

TABLE II.—*Medium Estimates of Future Population by Subregions*
(in 000,000)

Region	1960	1975	2000
Low-latitude South America	107.0	163.0	339.0
Middle-latitude South America	32.9	41.7	55.8
Latin America as a whole	205.8	304.1	592.8

Source: Population Branch, United Nations.

The decrease in the death rate that has taken place in all the Latin American countries is essentially the result of the improvement of medical services and of public hygiene and has accompanied the decrease of illiteracy. The virtual elimination of malaria, the great decrease in smallpox cases, the effective attack on yellow fever and hookworm—all these medical gains have had the effect of saving the lives of children.

The population of South America is quite diverse in its racial composition. There are certain countries in which the proportion of Indians remains high. In Ecuador, Peru, Bolivia, Paraguay, and the southern part of Colombia, people of unmixed or almost unmixed Indian ancestry make up more than half of the population. In Argentina, Uruguay, and southern Brazil (from São Paulo state southward) the population is more than 95% pure European in origin. It is to this part of Brazil and to Argentina that the great stream of European immigration into South America has gone.

Since 1800 an estimated 12,000,000 immigrants have arrived in Latin America. Of these about 4,000,000 came from Spain, 4,000,000 from Italy, and 2,000,000 from Portugal. The remainder include a variety of peoples: Germans, Poles, and other Europeans; Syrians; Chinese; and Japanese. There are also parts of South America in which there is a high proportion of Negroes. The Negroes came first to the Portuguese colonies of Salvador and Recife in northeastern Brazil to work the sugarcane plantations established there during the 16th century. This area still has a large proportion of Negroes and mulattoes. After the beginning of the 18th century, when gold and diamonds were discovered in Minas Gerais, many Negroes were brought as slaves to that part of Brazil; this region thus contains a considerable proportion of Negroes in its present-day population. Similarly, deep in the interior, near Cuiabá, there is a concentration of Negroes around old colonial goldworkings. Negroes were also brought as slaves to sugarcane areas in Venezuela and in the Cauca Valley and Caribbean coastal lowlands of Colombia. Elsewhere, the population of South America is a mixture chiefly of Indians and Spaniards known in Spanish America as mestizo. Table III gives the best available estimates of racial proportions.

TABLE III.—*Estimated Racial Proportions*
(in %)

Country	European	Indian	Negro	Mestizo	Oriental
Argentina	97	3			
Bolivia	15	53		32	
Chile	30	5		65	
Colombia	20	7	5	68	
Ecuador	15	60	3	22	
Paraguay	(97% Indian and mestizo)				
Peru	15	46		38	1
Uruguay	90		2	8	
Venezuela	20	7	8	65	

Throughout Latin America there is a tendency for the densely

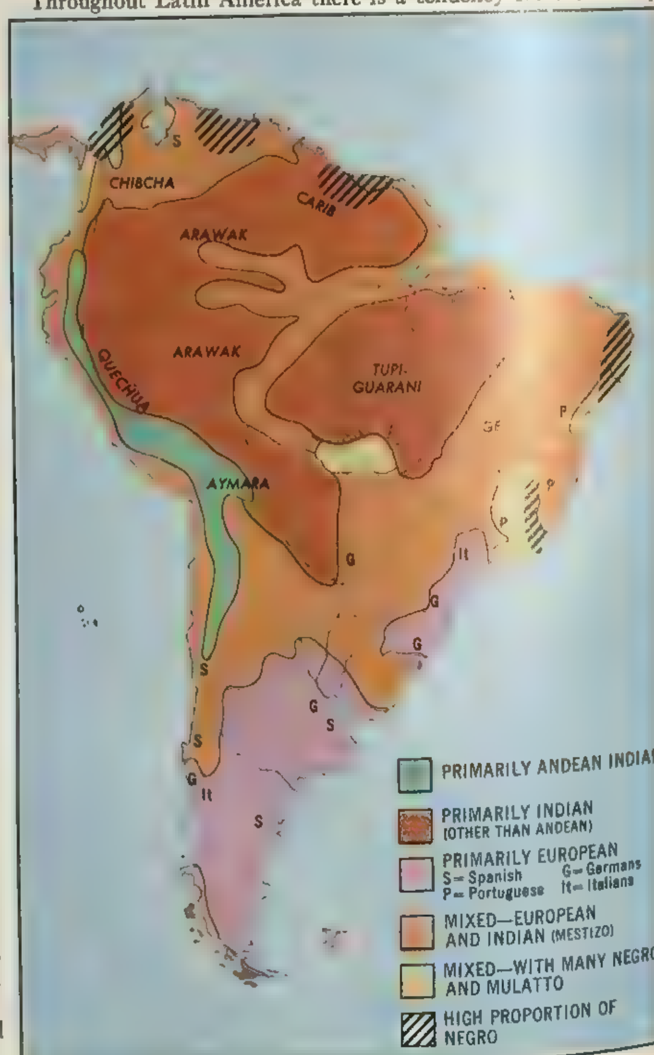

FIG. 6.—RACIAL COMPOSITION OF SOUTH AMERICA

populated areas to increase in population more rapidly than the average and for the thinly peopled areas to become even more sparsely populated. There are, to be sure, a few zones of pioneer settlement where new lands are being cleared and settled, but by far the greater part of the population movement is away from these frontiers rather than toward them. The movement generally is from the rural areas into the cities. Urban growth, especially after World War II, increased rapidly. The first city in South America to reach a population of 1,000,000 was Buenos Aires in 1906. Since then Rio de Janeiro, São Paulo, Santiago, Lima, Caracas, Bogotá, and Montevideo have all passed this mark. Not only have the cities increased in size, but also the proportion of the total population of each country living in the central cities has increased. This urban growth is a measure of the rapidity with which the Industrial Revolution is sweeping over Latin America. (P. E. J.)

V. HISTORY

When the mainland of South America was sighted by Columbus on his third voyage, in 1498, it was inhabited by numerous Indian tribes of widely varying cultures. By 1560 Spain had overrun much of the continent, conquered a large majority of the native inhabitants, discovered mines that gave the area a firm economic base, established the Roman Catholic Church, and evolved an administrative system that did not undergo any major modification until the 18th century, when threats from Great Britain forced a reorganization. Meanwhile, the Portuguese in Brazil developed a tropical-agriculture colony based upon Negro slavery. The British, French, and Dutch established their claims to certain of the "leftover" areas of the continent in the 17th and 18th centuries.

The Spanish colonies won their independence as a result of a costly 15-year struggle (1810–25), while Brazil separated from Portugal with a minimum of effort in 1822–23 and formed an empire, which lasted until 1889.

For approximately one century after political freedom had been won, the Spanish republics were ruled—often by force—in the interest of a narrow elite. After 1875, European immigrants and foreign capital and technicians contributed significantly to the material development of the nations.

Since World War I, several of the republics have undergone major transformations. New middle classes and working classes have emerged and have been incorporated into the political life. Economically, the republics have sought, with some success, to widen the range of their production and have made the modern factory the symbol of progress. For a full treatment of the history of South America, *see* LATIN AMERICA. *See* also references under "South America" in the Index. (J. J. J.)

SOUTH AMERICAN LANGUAGES. South America and the West Indies apparently had more than twice as many aboriginal languages as were found in Central and North America. It seems also that the South American languages were more diverse than those to the north. Linguists have enumerated no more than 40 distinct stocks from Central and North America, but the estimated number of stocks for South America range from 70 to more than 100. The aboriginal languages of the West Indies belonged to two stocks, Arawakan and Cariban, both of which became widespread in South America. (For a general discussion of the languages of the Americas and a brief description of the methods of classifying languages into stocks or families, *see* AMERICAN ABORIGINAL LANGUAGES; *see* also CENTRAL AND NORTH AMERICAN LANGUAGES.)

It is probable that the extreme linguistic diversity noted for South America rests in large part on two factors: (1) a lack of detailed knowledge of most South American languages; and (2) a method of classification based mainly on the comparison of brief vocabularies which is wholly inadequate for the establishment of more distant relationships. It seems that when more is known of the languages of South America and proper methods can be applied to their classification, the number of stocks will be considerably reduced.

The larger and the more widely distributed linguistic stocks of South America and the West Indies appear to fall into the following groups:

1. Chibchan. These languages, in the aboriginal period (*i.e.*, roughly A.D. 1500 and before), occupied most of Colombia, and extended southward to the latitude of Guayaquil in Ecuador and northward to include Panamá and most of Costa Rica and Nicaragua. One of the languages served a powerful Indian empire, with its centre near Bogotá. Later, but before the Spanish conquest in 1533, this empire was defeated by the Incas of Peru and the southernmost Chibchan languages were driven back or replaced by Quechuan languages (*see* no. 6, below). A number of Chibchan languages are still spoken, mainly by small Indian groups in Colombia and Central America, but these are gradually giving way to Spanish.

Some investigators (notably J. Alden Mason, 1950) proposed a Macro-Chibchan stock, composed of Chibchan plus the Misumalpan languages of Central America (*see* CENTRAL AND NORTH AMERICAN LANGUAGES). The evidence for this grouping is weak.

2. Cariban. This group spread, in preconquest times, from the Greater Antilles to central Mato Grosso in Brazil, and from eastern Peru to central Pará, Braz. Most of the languages, however, were found north of the Amazon River, in the territory now occupied by northern Brazil, the inland areas of the Guianas and Venezuela and lowland Colombia.

West Indian Cariban is extinct, but a considerable number of Cariban languages, perhaps as many as 200, have survived.

3. Arawakan. This is the largest and most widespread of all South American linguistic stocks. During preconquest times, Arawakan languages were found, in a number of disconnected areas, from Cuba and the Bahamas southward to the Gran Chaco and the sources of the Xingu River in southern Brazil, and from the mouth of the Amazon River to the eastern foothills of the Andes. Some of the languages of this group are extinct or nearly so (particularly in the West Indies), but more than 200 are still spoken in South America.

4. Ge. The languages of this group, in modern and aboriginal times, occupied a solid large area in eastern Brazil. About 50 languages survive, although most of these are slowly being replaced by Portuguese. Mason (1950) combined Ge and eight smaller stocks spoken near it into a Macro-Ge grouping, which, in his terms, was still "far from proven." The eight added stocks were Caingangan, Camacanian, Machacalian, Purian, Patacho, Malali, Caropa, and Botocudo.

5. Tupí-Guaraní is the second largest linguistic stock of South America. It has two major divisions: Tupian, spoken in eastern Brazil, mainly along the coast from Uruguay to the mouth of the Amazon, and inland along the Amazon to the foothills of the Andes; and Guaranian, spoken in Paraguay and the neighbouring region of Argentina.

Languages of both divisions were used by the first European traders and missionaries as contact languages in their dealings with the Indians. About 120 Tupí-Guaraní languages are still spoken, but these, as well as the two more widespread contact languages, are slowly giving way to Portuguese and Spanish.

Macro-Tupí-Guaraní, proposed very tentatively by Mason (1950), combines Tupí-Guaraní with two smaller stocks, Huitoto-Miranyan and Zaparoan in eastern Ecuador and Peru.

6. Quechuan. Archaeological and historical studies suggest that the Quechuan languages probably occupied a small area in the southern Peruvian highlands until, about 1450, they were spread over a far larger region by the rapid conquests of the Inca empire. When Pizarro conquered the Incas in 1533, Quechuan languages were spoken over most of the west coast of South America, from southern Colombia to central Chile, and eastward from the coast to the borders of the Amazonian basin. Quechuan languages are still spoken by several million people in roughly the same area, many of whom speak no other language. Nevertheless, the Quechuan languages are slowly losing ground to Spanish, which, by reason of its position as the language of government and education, plays an increasingly important role throughout the area. The modern Quechuan languages, about 28 in number, are said to be very much alike.

7. Aymaran. The languages of this group were spoken over a fairly large region in the southern Peruvian highlands and adjacent areas of Bolivia. Inca conquests probably reduced the Aymaran area somewhat, but there remain almost 500,000 speakers of the 14 Aymaran languages.

J. Alden Mason (1950) suggested that Quechuan and Aymaran might be combined into a single stock, which he called Quechumaran. The evidence for this relationship is not impressive.

Many of the remaining languages of South America are grouped into 45 stocks, which are more restricted in size and distribution than the ones listed above. These are:

In Venezuela: Chirianan, Cuica-Timote, Guahiban, Guarauan, Jirajaran, and Salivan.

In Colombia: Mocoa, Pamiguan, Puinavean, and Tucanoan.

In Brazil: Arauan, Borotuque, Carajan, Caririan, Catuquinan, Guaitacan, Huanhaman, Muran, Nambicuran, Panoan, Peba-Yaguan, and Zamucoan.

In Ecuador: Canelan, Jivaroan, and Omurano.

In Peru: Aguanoan, Cahupanan, Munichean, Sabelan, and Yunca-Puruhan.

In Bolivia: Chapucuran, Chiquitoan, Mosetenan, Tucanan, and Yurucarean.

In Paraguay (and adjacent parts of Brazil and Argentina): Guaycuruan, Mascoian, and Mataco-Maca.

In Chile: Alacalufan, Araucanian, and Ataguitan (also in adjacent parts of Argentina).

In Argentina: Chon (or Tehuelchean), Comechingonan, Huarpean, and Lule-Vilelan.

This listing by no means accounts for all the languages of South America. P. Rivet and C. Loukotka (1952) listed 108 stocks—the list above contains only *52*. But the additional "stocks" were actually very little known: McQuown estimated (1955) that there were over 600 languages in South America on which there were too little data to permit even a tentative classification. (*See* also INDIAN, LATIN AMERICAN.)

South America is unmatched in its linguistic diversity. The classification given above must therefore be regarded as highly tentative, and subject to drastic revision when better knowledge of the area becomes available.

Cohen, *Les Langues du monde* (1952). (H. HR.)

SOUTHAMPTON, HENRY WRIOTHESLEY, 3RD EARL OF (1573–1624), Shakespeare's patron, was born at Cowdray, Sussex, on Oct. 6, 1573. He succeeded his father in 1581 and became a royal ward under the care of Lord Burghley. Educated at St. John's College, Cambridge, and Gray's Inn, London, at 17 he was presented at court, where he was favoured by the queen and befriended by the earl of Essex. Southampton became a munificent patron of poets: Barnabe Barnes appended a sonnet in his honour to *Parthenophil and Parthenophe* (1593); Thomas Nashe dedicated *The Unfortunate Traveller, or, the Life of Jack Wilton* (1594) to him; and Gervase Markham his poem on Sir Richard Grenville's last fight (1595).

BY COURTESY OF THE NATIONAL PORTRAIT GALLERY, LONDON

HENRY WRIOTHESLEY, 3RD EARL OF SOUTHAMPTON. AFTER A PORTRAIT BY D. MYTENS, ABOUT 1618

Southampton is best known, however, as the patron of Shakespeare, who dedicated *Venus and Adonis* (1593) and *The Rape of Lucrece* (1594) to him. It has also been argued, inconclusively, that the sonnets were addressed to him (*see* SHAKESPEARE, WILLIAM: *The Poems: The Mystery of "Mr. W. H."*). If so, the earlier sonnets, urging marriage, must have been written before the beginning in 1595 of Southampton's intrigue with Elizabeth Vernon, one of the queen's waiting women, which culminated with their hasty marriage in 1598, incurring the queen's wrath and leading to their brief imprisonment.

Meanwhile in 1596 and 1597 Southampton had accompanied Essex on his expeditions to Cádiz and to the Azores. In 1599 he went to Ireland with Essex, who made him general of his horse, but the queen insisted that the appointment be canceled, and Southampton returned to London. He was deeply involved in the Essex Rebellion, on the eve of which he induced players at the Globe Theatre to revive *Richard II*, a play dealing with the deposition of a king, in order to stir up the populace. He was tried for treason on Feb. 19, 1601, and condemned to death, but his sentence was commuted to life imprisonment through the intervention of Sir Robert Cecil.

On the accession of James I, Southampton resumed his place at court. He was made a knight of the Garter and captain of the Isle of Wight in 1603, and was restored in blood by act of Parliament in 1604. In 1603 he entertained Queen Anne with a performance of *Love's Labour's Lost* by Richard Burbage and his company, to which Shakespeare belonged.

Southampton was an active member of the Virginia and East India companies. A born fighter, he was engaged in more than one serious quarrel at court and was imprisoned for a short time in 1603. He was a volunteer in support of German Protestants in 1614, and in 1617 proposed fitting out an expedition against the Barbary pirates. He became a privy councilor in 1619 but fell into disgrace through his determined opposition to the favourite, the duke of Buckingham. In 1624 he and his elder son volunteered to fight for the United Provinces against Spain, but on landing they were attacked with fever, and Southampton died at Bergen op Zoom on Nov. 10, 1624, a few days after his son.

See "Memoirs of Henry Wriothesley, the third Earl of Southampton," in James Boswell (ed.), *Shakespeare* xx, pp. 427 ff. (1821); A. L. Rowse, *Shakespeare's Southampton* (1965). (RD. C. G.)

SOUTHAMPTON, THOMAS WRIOTHESLEY, 1ST EARL OF (1505–1550), English civil servant and lord chancellor, was born in London on Dec. 21, 1505. The son of one herald, William Writh or Wriothesley, and nephew and cousin to two others, Thomas was well-placed for a career in the royal service. He was educated at Cambridge where he made the acquaintance of Stephen Gardiner, later master of Trinity Hall, bishop of Winchester, and a leading councilor to Henry VIII. Wriothesley subsequently married Gardiner's niece Jane Cheyne. Gardiner appointed him a clerk of the signet in 1530, but when Thomas Cromwell rose to power (1532–33) Wriothesley transferred to his service, finally becoming Cromwell's chief clerk and personal secretary. His promising connections not only got him possession of extensive monastic properties in Hampshire and elsewhere, but also moved him upward in the king's service. In 1538 he went on embassy to the Netherlands; in 1539 he sat in Parliament as one of the knights for Hampshire; in April 1540 he succeeded Cromwell as one of two joint principal secretaries of state. In the same month he was knighted. Cromwell's fall (June 1540) did not interrupt his career; indeed, even before the final crisis he had almost certainly reestablished contact with Cromwell's enemy Gardiner and had worked against his master. Wriothesley was a true Henrician who would have nothing to do with the pope and welcomed the dissolution of the monasteries, but remained a conservative in religion and viewed with apprehension Cromwell's negotiations with the Lutheran states. After Cromwell's fall the dearth of able administrators gave Wriothesley his chance. From 1542 he was one of Henry VIII's leading councilors, rewarded with a barony in January 1544 and (surprisingly, since he was neither a lawyer nor an ecclesiastic) with the lord chancellorship, the senior office of state, in April that year.

Boundlessly ambitious, he hoped to profit from the accession of a minor after Henry VIII's death (January 1547), but the ensuing political struggles proved that he should have remained the senior civil servant the discerning Cromwell had meant him to

be. In February 1547 Protector Somerset bought his support with the earldom of Southampton; a month later, ready to promote the Reformation, Somerset deprived him of the chancellorship. Naturally, therefore, Wriothesley supported the conspiracy which Somerset's rival, John Dudley, earl of Warwick (later duke of Northumberland), led against Somerset in October 1549. But once again he was outmaneuvered: so far from restoring the old religion and the fallen minister, Warwick proved more Protestant still and in February 1550 excluded Wriothesley from the Council. The earl died in London on July 30, 1550. An assiduous and efficient servant to others, he was negligible as a statesman, being gifted with neither vision nor originality nor even competence in the intrigues in which he engaged with such fervour.

(G. R. E.)

SOUTHAMPTON, a port, city (1964), county borough, and parliamentary borough of Hampshire, Eng., lies 76 mi. SW of London by road. Pop. (1961) 204,822. Area 15.1 sq.mi. The town stands near the head of Southampton Water, an inlet of the English Channel, on a peninsula formed by the Rivers Test and Itchen. It is the third largest in importance among English ports and the first in regard to passenger traffic. In A.D. 43 there was a Roman settlement, Clausentum, on the east bank of the Itchen, and inscribed stones, coins, pottery, etc., have been found. Southampton (Hamtune, Suhampton) superseded the Saxon Hamtune and was a royal borough before 1086. The earliest town charter was given by Henry II, probably in 1154–55, but the borough was not incorporated until 1445. Henry VI, in 1447, created Southampton a county in itself. A charter which remained in force until 1835 was granted by Charles I in 1640. It was from Southampton that the Mayflower sailed with the Pilgrim Fathers to America. The town has returned two members to Parliament since 1295. It is a quarter sessions borough. Southampton gives name to a bishopric suffragan to Winchester. Natives of the town include Isaac Watts (1674–1748), Sir John Millais (1829–96) and Earl Jellicoe (1859–1935).

An old house known as King John's Palace is one of the earliest 12th-century domestic buildings in England. The south (God's House Gate) and west town gates date from the early 14th century; Bar Gate (the north gate), as it stands, is mostly later and retains good Decorated work. St. Michael's Church has an 11th-century tower and arches and a font of Tournai marble (*c.* 1150). The priory of St. Denys, an Augustinian foundation of 1124, gives its name to a suburb by the Itchen. Netley (*q.v.*) Abbey is 3 mi. southeast.

The old guildhall, long used as a courthouse, is over the archway of the Bar Gate. Tudor House, a medieval merchant's residence, is the museum. King Edward VI Grammar School was founded in 1550, Taunton's School in 1760; the University College of Southampton, evolved from the former Hartley Institute, received its charter as a university in 1952. The town suffered severely from air raids in World War II, three-quarters of the old district in the centre having been devastated and important port installations destroyed. The civic centre, completed in 1939, comprises the new guildhall, municipal offices, police headquarters and law courts, and the public library and art gallery. The tower is a landmark for shipping and contains a clock and bells. There are a large sports ground (268 ac.), a common, and several parks.

The Port and Its Trade.—The modern importance of the port began with the creation of a pier and harbour commission in 1803 and the erection of the Royal pier in 1831. The prosperity of the town was enhanced by the opening of railway communication with London in 1840. The fine natural harbour has the advantage of a double tide. In 1950 the docks were taken over by the Docks and Inland Waterways Executive. The older docks lie at the confluence of the Test and Itchen rivers; large modern extensions lie to the northwest of these alongside the Test River. The old docks cover more than 200 ac. and in addition to the river quays there are three large tidal basins, the Ocean dock, Empress dock, and the Outer dock, leading to the Inner dock. The new docks, with 1½ mi. of deep-water quay facing the Test River, include the King George V dry dock, one of the largest in the world.

Southampton is England's chief port for express transatlantic services and is also used by ships bound for South America, East Africa, Australia, New Zealand, and the Far East. There are cross-channel services by British Railways ships and a ferry to the Isle of Wight. Southampton Airport is at Eastleigh, 5 mi. northeast.

Principal industries are shipbuilding and ship repairing, building and contracting, dock and harbour services, distribution services, and marine engineering. There is also a wide range of light industries. A large new oil refinery was opened at Fawley on Southampton Water in 1951.

SOUTH ARABIA, an area on the southern coast of the Arabian Peninsula, bounded on the west by Yemen, on the north by Saudi Arabia, on the east by Muscat and Oman, and on the south by the Gulf of Aden. The area was named the Aden Protectorate in 1937 and renamed the Protectorate of South Arabia in 1963; it is under the protection of Great Britain. Area (including the island of Socotra, lying at the mouth of the Gulf of Aden, opposite Cape Guardafui in Somalia) about 112,000 sq.mi. (290,000 sq.km.); pop. (1965 est.) 868,000. The protectorate is divided into Western (pop. 550,000) and Eastern (pop. 318,000) areas.

The Western protectorate includes 'Abdali (sultanate of Lahij), 'Alawi sheikhdom, 'Aqrabi sheikhdom, 'Audhali sultanate, Upper 'Aulaqi sultanate, Upper 'Aulaqi sheikhdom, Lower 'Aulaqi sultanate, amirate of Beihan, Dathinah state, amirate of Dhala ('Amiri); Fadhli sultanate, Haushabi sultanate, Lower Yafa'i sultanate, Upper Yafa'i sultanate, Sha'ibi sheikhdom, and Wahidi sultanate (Balhaf), together with five small sheikhdoms in the Upper Yafa'i area (Bu'si, Dhubai, Maflahi, Mausatta, and Hadhrami). The colony of Aden (*q.v.*) is on the coast of the Western Protectorate.

The Eastern Protectorate comprises the Qu'aiti sultanate of Shihr and Mukalla, the Kathiri sultanate, and the Mahra sultanate of Qishn and Socotra.

Physical Geography.—South Arabia extends from Ash Shaykh Sa'id, which marks its boundary with Yemen, eastward for about 740 mi. (1,190 km.) to Ra's ("cape") Darbat 'Ali, which marks that with Oman. The southern coastal strip varies in depth from 4 to 40 mi. (6.4 to 64 km.). There are some fertile parts, but in the main it is sand and lava. Behind this plain in the west are mountain ranges varying from 1,000 to 2,000 ft. (300 to 600 m.) and rising to a plateau of from 5,000 to 8,000 ft. (1,500 to 2,400 m.). This merges into the Yemen Highlands and falls away on the east to the sands of the Rub' al Khali. In the east the main feature is the extensive *jol* (plateau) of the Hadhramaut (*q.v.*), varying from 3,000 to 6,000 ft. (900 to 1,800 m.) which also falls away to the Rub' al Khali in a series of steppes. The mountain ranges of the west and the plateaus of the east are dissected by wadis (valleys) which bring down torrents from the Yemen and make limited agriculture possible.

The warm season lasts from May to September, with the southwest monsoon; the cool season from October to April, with the northeast monsoon. The average annual rainfall is about 1 in. (25 mm.) in the maritime region, and rather more inland.

The People.—Population estimates since 1934 have varied from 600,000 to 1,000,000. Almost all are Arabs and Sunni Muslims; ethnically those in the west are of Mediterranean stock, with pockets of Veddoids increasing eastward until in Mahraland virtually all are Veddoid. The Mahras speak a non-Arabic Semitic language and for that reason are not recognized as Arabs. In 1946 the population of Aden and the protectorate was estimated as 70% tribesmen, all armed, and 30% townsmen.

The social organization has been shaped by desert conditions and by Islam. Thus the descendants of the Prophet (mostly through his grandson Husain and called Sayyids) rank highest socially. The tribesmen are the most important single factor in society, for they are armed and in the majority. Townsmen, ranging from important merchants down to *dhafa* (mostly artisans), are unarmed. Truly urban conditions exist only in such towns as Lahij and Al Mukalla, where social conditions resemble those of Aden on a small scale. (*See* further ARAB.)

History.—The presence of Paleolithic and Neolithic artifacts is evidence that the country was populated in prehistoric times, but history really begins after 6000 B.C. when desiccation set in after

the retreat of the last Ice (here Pluvial) Age. The desert conditions turned the inhabitants, whatever their racial origin, into Arabs, attuned to a nomadic life. Tribal life began to evolve, and gradually four main regions developed: Saba, Qataban, the Minaean Kingdom, and the Hadhramaut (*see* further SABAEANS; ARABIA: *History: The South Arabian Kingdoms*).

Cities and the first civilization in Arabia developed in South Arabia from the trade in incense, the demand for which was great. It grew in the Hadhramaut and in regions east of it, and other peoples became rich on the overland carrying trade. The cities fell into ruins, however, and their citizens reverted to tribal life when the Romans ruined the overland trade by taking incense by sea. From that time onward conditions of tribal life continued in South Arabia, though from time to time the tribes fell under the control of dynasties based in the Yemen (*q.v.*).

The modern history of South Arabia can be said to date from 1839, when the British East India Company occupied Aden. This caused considerable uneasiness to the neighbouring tribes, which valued their independence but realized their weakness. However, the political agent of the East India Company and the Bombay government pursued a consistent policy of good relations, and to that end made agreements with six neighbouring chiefs in 1839. In the early 1880s the British and Indian governments agreed to the negotiation of protectorate treaties; the first were made in 1886. With confidence established, the number of treaties increased. All the protected territories were recognized by the Anglo-Turkish Convention in 1914 as within the British sphere. Finally a protectorate order-in-council in 1937 formally constituted the territories of the treaty chiefs into a "protectorate," and the Aden Protectorate acquired a legal existence and became the responsibility of the British Colonial Office rather than of the British Government of India.

Noninterference with the internal affairs of the tribes had over a long period developed into established policy, and it was continued after 1937; it had succeeded in making the protectorate a *cordon sanitaire* for Aden. In 1934 close contact had been made for the first time with the Hadhramaut, and some 1,400 tribes and tribal groups, constantly warring or marauding, were in 1937 persuaded to join in a general truce. In the following year the protectorate was divided administratively into the Eastern and Western Aden Protectorates. This was followed by the two principal chiefs signing advisory treaties (by which they undertook to accept the advice of a resident adviser). Thereafter formal government was organized without interfering with the internal affairs of some 2,000 tribal and other autonomous petty rulers. In 1944 advisory treaties in more restricted terms were introduced in the Western protectorate, and by the late 1940s a far more rigid regime became evident. The margin between advice and direct administration was often imperceptible, and military and air action to reduce some tribes to obedience increased.

In January 1954 federation was proposed to the chiefs but was not welcomed. However the British "forward policy" (the antithesis of the traditional "noninterference" policy) in regard to the protected states had been regarded by the imam of the Yemen as an infringement of the *status quo* agreed to in the Treaty of San'a' (1934), and he had begun what was virtually a war, supported by Egypt and some Communist countries. By 1958 the chiefs were so alarmed that six agreed to federate. In February 1959 Britain and the federation signed a treaty which recognized the latter's desire to develop into an independent state which Britain would assist it to achieve. It also extended protection and provided for the acceptance of advice. A new capital was founded on the Aden border in October and named Al Ittihad ("unity" or "concord"). By the end of 1962 five more chiefs had joined and in January 1963 Aden colony also joined, though remaining under British sovereignty. By 1965 all treaty chiefdoms except four had been induced to join and the total membership (including Aden) was 17 states.

In July 1964 the British government announced that the federation (including Aden) should become independent not later than 1968. Thereafter a succession of political and constitutional difficulties arose and little progress was made in negotiations. During 1964–66 there was also a considerable increase in Yemeni terrorist activity, largely inspired and assisted by Egypt.

Administration.—The transfer of responsibility for Aden and the protectorate to the Colonial Office in 1937 led on to the policy of federation, but deeply entrenched traditional forces still largely prevail internally. The constitution introduced in December 1962 gave legislative and executive authority to the federal government in a number of matters, particularly education and agriculture. In 1963 the governor became a high commissioner, and the order-in-council that gave legal force to the constitution made his authority prevail over the federation's in matters of defense, internal security, and external affairs. The legislature is the Federal Council; Aden has 24 members in it, and most of the other states 6 members each. The executive is the Supreme Council, consisting of those ministers prescribed by federal law and elected from the Federal Council and up to three other members appointed by the ministers and confirmed by the Federal Council. States represented in the Federal Council by at least six members can claim one minister for every six representatives. Ministers hold the chairmanship for one month in rotation.

Each state is self-governing, with such executive and legislative authorities as it may decide. One state, Dathinah, is a republic.

Social Conditions.—The conditions of society derive largely from the traditional social organization. Up to the late 1940s formal education other than religious virtually did not exist outside the Qu'aiti and 'Abdali states, but by the mid-1960s the Western Protectorate had about 7,500 places for boys and nearly 800 for girls at the primary level and for over 700 boys at intermediate level. Education for girls at that level did not begin until 1963. In the Qu'aiti and Kathiri (unfederated) states there were, in that year, 10,700 primary places for boys and girls and 11 intermediate schools. There is a secondary school at Al Mukalla and a teacher-training college at Ghayl ba Wazir which serves both states.

Outside Al Mukalla there were by the mid-1960s eight protectorate hospitals served by 25 doctors and linked to 76 rural health units. The health service was expanding.

The Economy.—Agriculture is the principal occupation, but a comparatively small area is cultivable. The most widely grown crops are millets and other small grains; some wheat and barley are grown at the higher levels. Dates are grown wherever possible, and in the Western Protectorate some coffee, particularly in the mountains of Yafa'. Herds are limited in number and quality by inadequate grazing, but there are more than 1,000,000 sheep and goats, about 70,000 cattle, 80,000 camels, and 13,000 donkeys.

Of cash crops tobacco from the Qu'aiti state was formerly the most important but has been superseded by cotton. By the mid-1960s cotton production from the Abyan Oasis, Lahij, and smaller areas was approaching 40,000 bales.

The growing of fruit and vegetables for the Aden market, first encouraged in Lahij in the 19th century, has greatly expanded, and there is a modern fruit and vegetable wholesale market at Khormaksar in Aden. Much has been done to develop the fishing industry, and many local craft are now power-driven. *See* also ADEN; ARABIA; HADHRAMAUT. (W. H. Is.)

SOUTH AUSTRALIA, a state of Australia in the central portion of the continent, occupying 380,070 sq.mi. (984,395 sq.km.), or about one-eighth of the total area. In the north the boundary runs successively with those of the Northern Territory and Queensland along latitude 26° S and in the east with those of Queensland, New South Wales, and Victoria along longitude 141° E. In the south the state has an irregular coastline (its only natural boundary), about 2,200 mi. (3500 km.) in length, and in the west the boundary marches with that of Western Australia along longitude 129° E. The state capital is Adelaide (*q.v.*).

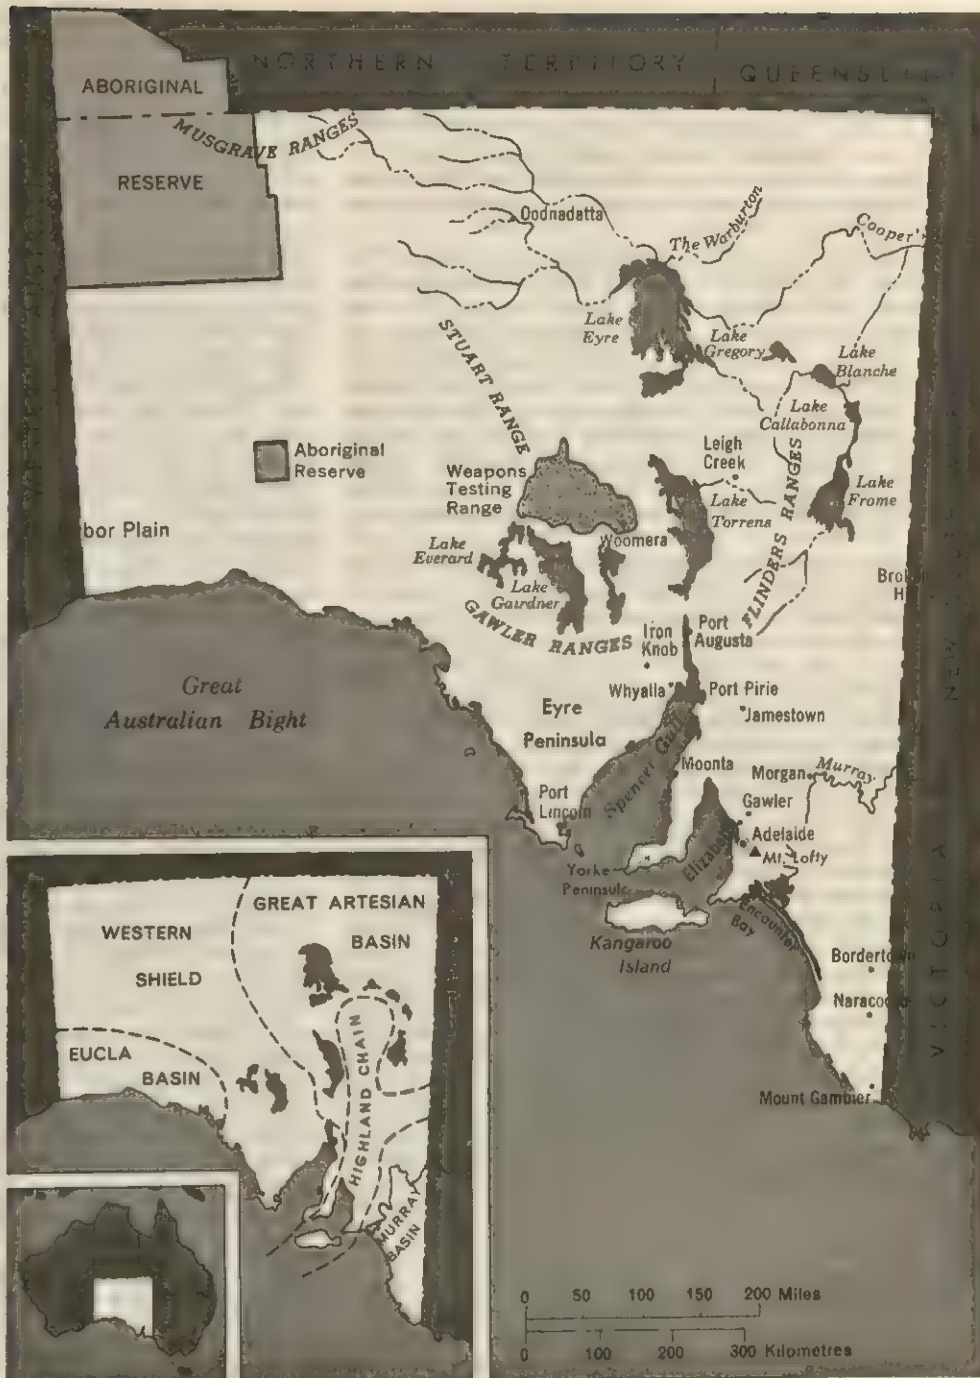
PHYSICAL GEOGRAPHY

Physical Features.—Situated athwart the junction line of the western plateau and the great central lowland of Australia, South Australia can be divided into a number of different physical regions. Its relief is nowhere so marked as that of the eastern states, and there is relatively little land above 2,000 ft. (600 m.). There are

five major physical regions: the western shield; the highland chain; and three sedimentary basins—the Eucla Basin in the far southwestern corner of the state, the Great Artesian Basin in the northeastern corner, and the Murray Basin in the southeast.

Most of the western part of the state is occupied by the eastern portion of the western shield. This extends from the Musgrave ranges in the northwest to the western portion of the Yorke Peninsula in the southeast and consists mainly of Archean igneous and metamorphic rocks. The highland chain lies between the western shield and the Murray Basin and is the most prominent physiographic feature in the state. It includes the Flinders ranges in the north, the spur of the Main Barrier Range between the Lake Frome depression and the northern part of the Murray Basin, and extends southward through the Mt. Lofty ranges to Kangaroo Island and the eastern part of Yorke Peninsula. Most of the rocks in this highland chain are sediments formed in a geosyncline in late Proterozoic and Cambrian time; *i.e.*, more than 500,000,000 years ago.

The depressed area southwest of the western shield is occupied by the Eucla Basin, which extends into Western Australia. In the northeastern part of South Australia lies the southern portion of the Great Artesian Basin, probably the largest of its kind in the world. Beds of freshwater sandstones are the main aquifers and are thickest in the northern part of the state, lying at depths averaging from 4,000 to 5,000 ft. (1,200 to 1,500 m.). The southern part of the basin is occupied by the Lake Eyre depression, part of which is 39 ft. (12 m.) below sea level. South and east of Lake Eyre there is a series of lakes —Frome, Callabonna, Blanche, Gregory, Torrens, and Gairdner—which occupy a number of mud- and marsh-filled depressions. The Murray Basin lies in the southeastern part of the state and extends into western Victoria. On the whole it is a very flat area covered with Recent sediments. A series of low ranges of sand dunes runs parallel to the coastline. Around Mt. Gambier a few craters, occupied by lakes, have become tourist attractions.



MAJOR PHYSICAL FEATURES, CITIES AND TOWNS OF SOUTH AUSTRALIA

Climate.—The state may be roughly divided into two climatic regions: a northern warm, dry region with high summer temperatures and less than 10 in. (250 mm.) of rainfall per annum, much of which is erratic and unreliable; and a southern region typically Mediterranean with moist winters and hot, dry summers. Very few areas in this latter region receive more than 35 in. (900 mm.) of rain each year. North of the 32nd parallel and in the eastern part of the state north of the Murray River, the mean annual rainfall is less than 10 in., but, as in most dry areas, distribution is very erratic. Some sections may have 10 in. in a few months followed by years of almost complete drought. The driest known area of the whole continent occurs around Lake Eyre (*q.v.*).

South Australia is warm and sunny. In June, July, and August most of the state experiences mean monthly temperatures between 10° and 15.6° C (50° and 60° F). In the summer, however, the southern part of the state has mean monthly temperatures around 18.3° C (65° F), while in the northern part of the state the monthly average is between 26.7° and 29.4° C (80° and 85° F).

Soils.—The podzols, or ash gray soil, are found in the wetter parts of the state where iron oxide and other soluble materials have been leached out leaving the surface soil ash gray in colour and poor in plant nutrients. Where the rainfall is slightly less and the evaporation higher the podzols give way to the red brown earths, which extend north of Adelaide beyond Jamestown and in the southeast around Naracoorte and Bordertown and on Eyre Peninsula. All these areas are important for agriculture and grazing. The mallee soils, rich in lime but poor in humus and phosphate,

are closely associated with the mallee type of vegetation. With the application of superphosphate and some of the important trace elements (copper, zinc, and molybdenum), many of these mallee soils, once thought to be of little economic value, are gradually being sown down with subterranean clover, and it is expected that they will add considerably to the pasture acreage of the state. Desert-steppe soils and desert sand hills extend over the northern half of the state and are used for extensive grazing where artesian water is available.

Vegetation.—The natural vegetation consists mainly of five major types. Eucalyptus woodland and forest is on the higher and wetter parts of the Mt. Lofty and Flinders ranges and in the southeastern part of the state. Mallee (dwarf eucalypt), she-oak, and tea tree once covered the remainder of the southern portion of the state, but large areas of mallee have been cleared for agriculture. In the drier north the mallee gives way to mulga scrub (acacia), and on the fringe of the Nullarbor Plain in the west saltbush is dominant. In the northwest and northeast spinifex grass is the chief plant of the very dry areas, but in places there is no vegetation at all but only sandy ridges or rough gibber (stony) plains.

The great need for forest reserves was recognized at the end of the 19th century, and, although the total area set aside for forestry purposes is only 0.1% of the area of the state, more than 150,000 ac. were under plantation in the early 1960s, 95% of which were planted with soft wood. These man-made forests have changed the landscape of the southeastern part of the state.

Water Supply.—Climatic conditions made the provision of an adequate water supply an early problem for settlers in South Australia. Throughout the arid areas they were forced to rely on surface catchments for which large tanks were often constructed below ground level. Artesian water later became available, and the artesian wells are still a valuable source of water for the drier parts of the state. In the settled areas local water supplies have not been able to keep pace with the industrial and commercial developments, and it has, therefore, been necessary to draw on the resources of the Murray River. In 1944 the Morgan-Whyalla pipeline was completed to convey water 223 mi. from the bend in the Murray River at Morgan to the industrial area and shipping port at Whyalla on Eyre Peninsula. A branch was subsequently constructed to take water to the new settlement at the Long-Range Weapons establishment at Woomera, 110 mi. NW of Port Augusta. In 1954 the Mannum-Adelaide pipeline, capable of delivering 14,600,000 gal. per yr., was completed. In the 1960s further schemes were under consideration. It is estimated that 90% of the population of the state is dependent upon the Murray for its water supply. (G. H. Ln.)

HISTORY

The First Settlement.—South Australia was officially settled as a new British province on Dec. 28, 1836. Thirty-four years earlier the South Australian coast had been explored by Matthew Flinders, but no organized settlement had been proposed until 1830, when plans made by the National Colonization Society were placed before the Colonial Office. Later the South Australian Land Company and the South Australian Association also put forward plans. Each proposed to apply the Edward Gibbon Wakefield (*q.v.*) theory of systematic colonization in a new territory where settlers might enjoy civil and religious liberties, but each in turn was rejected by the government as "too republican." These frustrating negotiations ended in 1834 when an appeal to Parliament brought the South Australian Act, which guaranteed a fixed price for land and ensured that no convicts would be sent to the colony. To make certain that no cost would be borne by the mother country, the Colonial Office was to have charge of all government affairs except land sales, emigration, and fund raising, which were to be controlled by an independent board of colonization commissioners.

When settlement began, this division of authority led to bitter factional strife, exacerbated by the ill-considered rules of the commissioners in London. A site for the capital, Adelaide, was chosen and soon divided into quickly sold lots, but the survey of the country sections was unduly delayed, and very little food was produced until 1840. Some settlers thrived on speculation in town land and imported supplies, while thousands of poor immigrant families, heedlessly sent out by the commissioners, remained idle. As the commission had ordained a free market for labour, the first governor, Capt. John Hindmarsh, was powerless; the second, Col. George Gawler, exceeded his instructions by employing immigrants on costly public works. Before his unauthorized bills reached London, the commission was already bankrupt, its funds frittered away in "puffing" the new province. However, a parliamentary committee that examined South Australian affairs in 1841 blamed Gawler for the province's disastrous financial state. During the next year, Parliament paid most of the debts, stopped emigration, removed the colonization commissioners, and placed the province wholly under Colonial Office control.

Progress Toward Self-Government.—The third governor, Capt. George Grey, was pledged to economize. He arrived to find land surveyed and settlers at work on their country sections. By 1844 the colony was paying its way. Although wool was the chief export, farmers were growing more wheat than the population of 17,000 could consume. In 1845 rich copper discoveries brought a spectacular mining boom that made many settlers independent of the absentee investors who had hitherto financed and directed them from England. Local politics thus gained new interest and became more controversial. The Colonial Office was defied over mining royalties and road taxes, and when it insisted that state aid be offered to all churches, only four denominations accepted it. The vigorous protests of Nonconformists brought an end to government grants in 1851, making South Australia the first part of the British Empire completely to separate church and state. At the same time, four years of heavy immigration increased the population to 67,000 and qualified South Australia for the grant of a partially elected legislative council with the right of drafting a constitution of self-government.

The gold rush to Victoria had drawn thousands of South Australians when the first constitution was prepared in 1853. To returning diggers and irate citizens alike the constitution was "a caricature of self-government." Their petitions led to a second constitution, which provided two elective chambers: a House of Assembly with triennial elections, manhood suffrage, secret ballot, and no property qualifications; and a Legislative Council with a modest property franchise to protect landed interests. To the Colonial Office this was "the only thorough Benthamite constitution in the empire," but royal assent was given, and South Australia's first Parliament with responsible government met in 1857.

Political independence seemed to exhaust the colonists' ideas but not their powers of resistance. During the first 30 years of self-government there were 34 changes of ministry and very little experimental legislation.

One important early exception was the Real Property Act (1858), subsequently copied by more than 50 countries and sometimes called the Torrens Title System after its sponsor, Sir Robert Torrens (*q.v.*). To make conveyancing simple, quick, and cheap, the act replaced the unwieldy system of title deeds by one of certificates guaranteed by the state. In the courts the act was persistently challenged by Judge Benjamin Boothby, who claimed that it and other colonial enactments, including the constitution, were repugnant to English law. Boothby's stubborn stand soon led to his removal from the bench. To meet his objections the Imperial Parliament passed the Colonial Laws Validity Act (1865), which, by defining "repugnancy," became the legal keystone of the empire until the Statute of Westminster of 1931.

Economic Expansion.—By making titles secure the Real Property Act also simplified mortgaging, especially for wheat growers, whose small freeholds were beginning to force livestock owners farther afield in search of leases. Because pastoral expansion seemed to be checked by a barrier of salt lakes, exploration was stimulated. Slow-moving government parties found gaps between the lakes, and more mobile private explorers passed through them to find vast new pastures. The most notable of these pioneers was John McDouall Stuart, who finally crossed the continent in 1862, paving the way for South Australia's acquisition of the Northern Territory (1863) and for the overland telegraph,

which in 1872 linked Adelaide with the ocean cable terminus at Darwin. Other explorers found traces of minerals. In 1860 the discovery of rich copper lodes near Moonta aroused hopes of general prosperity and encouraged many pastoralists to move their stock beyond the salt lakes. Disaster followed, for the country was poorly watered; in the drought of 1864–65, thousands of sheep and cattle perished. As the drought did not extend very far to the south, Parliament was easily persuaded that all the southern areas were safe for agriculture.

During the gold rushes South Australian grain had fed the diggers in Victoria and followed them into New South Wales and Queensland. From 1853 steamboats carried flour far up the Murray and Darling rivers and returned with cargoes valuable enough to justify a railway and new port at Encounter Bay. In the mid-1860s an even greater market for grain was found in England. To the Parliament in Adelaide the prospect seemed brighter for wheat than for wool. In 1869 the Strangways Act introduced "credit land sales," by which the land hungry might acquire freeholds on expired pastoral leases on easy terms. A decade of prosperity followed. Immigration, heavily subsidized by the state, provided agricultural recruits and labour for the government's new railways. Each year brought new records in cultivation; yet South Australia, with one family in three on its farms, depended too much on agriculture for its economic well-being.

Hope and inexperience carried the farms into unsafe districts, and old overworked districts became "wheatsick." Though prosperity lasted until 1884, two droughts heralded collapse. Bankruptcies mounted as prices fell, banks failed, and copper mines showed signs of exhaustion. Average yields of 15 bu. per ac. dropped to less than 2 bu. Long before the economic depression ended, South Australia lost its lead in wheat growing to Victoria and New South Wales and fell behind Queensland in population. Numerous families migrated to eastern states, and many more were attracted to the towns even though urban industry had been neglected and employment was insecure. Demand for liberal reform stirred Parliament into action. Land in safe districts was offered on easy terms to homesteaders and workingmen. Promises of compensation encouraged pastoralists to improve their ranges and multiply their flocks. Water conservation projects were started; southeastern swamplands were drained; and irrigation and village settlements were begun on the Murray River. The opening of Roseworthy Agricultural College introduced farmers to the use of superphosphates, while scientific techniques began to produce better strains of wheat, freedom from disease, systematic fallowing, and more varied crops. Assisted immigration stopped, but railway building continued. To avoid further borrowing in London—the public debt was already close to £50 per head—in 1884 the government introduced for the first time in Australia direct taxation on incomes and land. When this proved insufficient, tariffs were sharply increased to curtail imports and foster urban industry. The opening of Broken Hill in New South Wales helped South Australia by providing employment for its miners, freight for its railways, and smelting works at Port Pirie, but these gains were at first offset by heavy migration to Western Australian goldfields. The high levels of production in 1884 were not regained again until 1906. Although the population had passed 300,000 by the mid-1880s, it did not reach 400,000 until 1910.

Political Parties.—The most marked advances of the depression years were in politics. Growing discontent brought the eight-hour working day (1884), payment of members of Parliament (1887), workmen's compensation (1889), industrial arbitration and votes for women (1894), and the first Australian use of a referendum (1895). Primary education, which had become compulsory and secular in 1875, was made free in 1891. The depression years also hastened South Australia's progress toward federation.

The tentative beginnings of a Labour Party during the 1890s forced its opponents into closer alliances and more stable ministries. Leading politicians, perplexed by inland tariff barriers, problems of the Murray River irrigation, and annual deficits in the Northern Territory, were eager for intercolonial cooperation. In the federal conventions South Australians played a leading part. Later, when the ablest leaders were drawn into the federal Parliament, local politics became more subdued. The Labour Party grew in strength and in 1905 took office in a coalition government. Its main concern was the reform of unequal electoral constituencies: Adelaide, with half the population, had only one-third of the seats in Parliament. Reform was resisted by the Legislative Council, whose abolition, though advocated by Labour, was not popular with electors. Nevertheless, the Labour Party did form occasional governments, most of them ending in dissension.

The postwar years brought the organization of the Farmers and Settlers' League, the Progressive Country Party, the Nationalists, and the Liberal Union. From these emerged the Liberal Federation and Country Party Alliance, which by 1933 forced Labour into apparently permanent opposition.

Economic Depression.—During the first decade of federation South Australia seemed to prosper. Its share of federal customs revenue paid the annual interest on the public debt, while bumper harvests and rising prices renewed enthusiasm for agriculture. Aided by new railways and superphosphates, farmers opened fresh wheat belts on Eyre Peninsula and in the southeast. Assisted immigration was resumed. Valuable iron ore deposits at Iron Knob were linked by rail with the new port of Whyalla. Port Adelaide was enlarged and an outer harbour added for mail steamers. Electric trams and suburban railways revived land speculation, while government high schools and free secondary education attracted families to the city.

The tide turned in 1910. Although the costly Northern Territory passed under commonwealth control, a new agreement for distributing federal revenue lowered South Australia's income. This was obscured at first by high prices for grain and wool during World War I and the early 1920s, but from 1914 to 1926 the government had to budget for eight deficits. State taxation quadrupled and government borrowing increased the public debt to £A136 per head (compared with Victoria's £A88). Large numbers of workers and some entire industries migrated each year to the eastern states where bigger markets, cheaper power, and lower taxes offered better opportunities. After 1928, four dry years coincided with worldwide depression to reduce the state to a worse plight than any of its neighbours. In the winter of 1931 more than 70,000 unemployed out of a population of 575,000 were dependent on government relief. Thousands of the unemployed sought work in the country, enabling a record crop of 8,000,000 ac. to be sown, although depressed prices gave farmers an average of less than *20s.* per ac. for their harvest. Appeals for federal aid led to the establishment of a Commonwealth Grants Commission and brought substantial assistance earmarked for developmental works. However, most politicians still looked to the land for salvation. To the auditor-general, W. Wainwright, this dependence on rural output seemed disastrous. He advocated more secondary industry: by judicious government guarantees to suitable enterprises the state would attract overseas investment and unlock its own private capital tied up in land. The threatened departure of a large motor-body-building industry forced the government to support Wainwright's plan. Certain wharf dues were abolished, and company tax was halved. The first large project was the planting of pine forests in the southeast, for the state had always depended on imported building timber. Guarantees were made to the cement and chemical industries at Port Adelaide. Elsewhere, industries were encouraged to make equipment for the expansion of roads, water supply, sewerage, and building. To supplement private efforts the government built large reservoirs for Adelaide, expanded technical education, and created a trust for housing industrial workers.

World War II and After.—In 1938 Thomas Playford began his long term as premier, and his accession infused new life into industrial policy. Some of his plans had strategic importance and were implemented during World War II. The Broken Hill Proprietary's new blast furnace and shipbuilding yard led to great expansion at Whyalla which had to be supplied with water by pipeline from the distant Murray River. Near Adelaide large munition works built by the commonwealth government were taken after World War II by overseas firms, some for new industries and others for the development of long-range weapons. The need for an iso-

lated testing site for the weapons brought the town of Woomera into existence, its water piped from the Murray. In 1946 Playford's government took over the private Adelaide Electric Supply Company, turning it into an electricity trust that cut prices and greatly expanded consumption. To make the state less dependent on imported fuels, the government opened a brown coal mine at Leigh Creek, and a large supplementary power station soon followed at Port Augusta. The postwar years also brought great rural expansion. Scientific testing of inferior soils revealed the absence of trace elements, which, when restored, gave fertility to much unused scrubland. Other marginal areas were opened by mechanization and improved techniques. High returns for wool and barley freed farmers from the vagaries of wheat markets, while road transport, diesel rail engines, and bulk handling of grain helped to produce new records in cultivation, pasture improvement, and sheep numbers. The most spectacular expansion, however, was in Adelaide. Its new and growing factories attracted a great influx of labour, which in turn demanded new homes and services. The city itself became dependent on water from the Murray. As the Adelaide Plain rapidly filled with buildings, a new satellite town was created nearby at Elizabeth. (D. H. PE.)

POPULATION

At the 1961 census the population of South Australia was 969,340 (excluding full-blooded aborigines who numbered 2,147), or about 9.2% of the total for Australia, compared with 797,094 at the 1954 census. During 1954–61 the population grew at the high rate of 2½ to 3% per annum, slightly more than half the increase being due to immigration. The fourth largest in population of the states of Australia, South Australia had in 1961 a density of about 2.6 persons per square mile. The population is heavily concentrated in the capital, Adelaide, which ranks fourth in size among Australian cities. The population of the Adelaide metropolitan area in 1961 was 587,957. The only country towns with populations exceeding 5,000 were: Elizabeth 23,326; Mount Gambier 15,388; Port Pirie 14,003; Whyalla 13,711; Port Augusta 9,711; Salisbury 9,349; Port Lincoln 7,508; and Gawler 5,639.

ADMINISTRATION AND SOCIAL CONDITIONS

Administration.—The constitution of South Australia vests legislative power in an elected Parliament comprising a Legislative Council and a House of Assembly. The Legislative Council consists of 20 members, half of whom retire every three years, being replaced by members elected for a term of six years from each of five electoral districts. The House of Assembly, elected for a period of three years, is composed of 39 members representing single electorates. Voting for elections to the House of Assembly is compulsory. Executive power is vested in a governor, appointed by the crown, and an executive council, which comprises the governor and the ministers of the crown. The local government authorities consist of district councils, municipal corporations, and cities.

Education.—South Australia has a comprehensive system of state education, with compulsory schooling until the age of 14 years. In addition to the state school system, a number of private schools have been established under church auspices. The principal institutions of higher education are the University of Adelaide and the South Australian Institute of Technology. There are also an agricultural college and teacher-training colleges.

Health and Welfare.—South Australia enjoys a healthful climate. The infant mortality rate of about 20 per 1,000 births is among the lowest in the world. The state is also fortunate in enjoying high standards of housing, and Adelaide has virtually no slums. At the 1961 census the number of persons per dwelling averaged only 3.5. In the early 1960s there were nearly 70 public and more than 150 private hospitals containing about 4,500 and 3,400 beds, respectively. Of these, the four major hospitals, which were in the Adelaide metropolitan area, contained a full range of facilities for diagnosis and treatment. Incomes in South Australia are comparatively high, and there are no great inequalities in the distribution of incomes. Average wages are about £A23 a week.

THE ECONOMY

Agriculture.—Although it is the third in size of the Australian states, South Australia has a relatively small area that can be utilized for agriculture. More than four-fifths of the total area has an average rainfall of less than ten inches a year and supports fewer than 2,000,000 sheep and 100,000 cattle.

In the higher rainfall areas sheep rearing and cereal production predominate. By the 1960s the sheep population of about 15,000,000 was nearly double the prewar figure and constituted 10% of the Australian total. More land was being put under pasture for livestock as a result of a wider use of subterranean clover, superphosphate, and modern mechanical methods of clearing. By these means, land previously considered useless, or able to carry as little as one sheep to four acres, was able to carry two sheep to the acre. The area sown to pasture increased more than eightfold after 1940.

For many years wheat has been the most important cereal in South Australia. A peak of 4,180,000 ac. was sown to wheat in 1930–31. Livestock then began to assume greater significance in areas formerly devoted exclusively to cereals, with the result that the wheat acreage has greatly declined. This decline has been partly offset by the expansion of the acreage under barley and oats, and in the early 1960s the value of barley output was almost as great as that of wheat. The total cereal acreage in the same period, however, remained only about half that of 1930–31. After World War II, wheat yields rose sharply, and in the early 1960s, at about 20 bu. per ac., they were almost double the yields of the 1930s.

Dairying is carried on mainly on the plains and in the hills within reach of Adelaide. The Angaston, Tanunda, Reynella, and Clare districts are noted for their excellent wines; South Australia produces three-quarters of the Australian output. Oranges, lemons, peaches, apricots, and almonds abound on the plains. By the Murray River citrus fruits, vine crops, and vegetables are grown under irrigation.

Mining.—Although South Australia is not rich in minerals, there are a number of important deposits. Most valuable are the large deposits of iron ore situated in the Middleback ranges, which are thought to amount to about 170,000,000 tons on the surface and so far have provided the bulk of ore for Australia's steel industry. This iron ore is of exceptionally high grade; it averages 62% iron and enables Australia to produce relatively cheap steel. Extensive exploratory campaigns were being undertaken in the 1960s to discover further deposits, and good-grade iron ore has been located underground. Attention was also being directed to the possibility of using the hematite-quartzites, of which the Middleback ranges are largely composed, for iron production. A proportion of the iron ore quarried in South Australia is converted into pig iron at Whyalla, where there is a modern blast furnace. By the late 1960s a fully integrated steelworks was to be established at Whyalla.

South Australia possesses abundant deposits of limestone and dolomite and a wide variety of clays. The state has no large coal deposits; the most important is at Leigh Creek, where about 55,000,000 tons of subbituminous coal is available for extraction by open-cut methods. This coal is used mainly for the production of electricity. South Australia produces four-fifths of Australia's salt requirements and contains the great bulk of the country's gypsum. The state also provides about nine-tenths of Australia's talc requirements and is the only source of opal.

Industry.—The industrialization of South Australia has taken place since World War II, and the manufacturing industry is now the state's main source of employment. At the 1961 census 27% of the work force was engaged in manufacturing, while only 12% was in primary production.

The chief features of South Australian industry are to be found in mineral processing and in automobile and consumer-durable production. Lead-silver concentrates are processed at Port Pirie in one of the world's largest lead smelteries, and sulfuric acid is produced at Port Adelaide. There is large-scale production of fertilizers and cement, and an oil refinery has been established near Adelaide. General Motors Holden and Chrysler Australia are the

main automobile producers, the former having its main Australian body-building works and the latter its principal plant in Adelaide. Around this key industry many subsidiary ones have developed. South Australia is the leading Australian state in the production of the larger household appliances, such as refrigerators, washing machines, and electric stoves, and in the production of tubes and pipes. A number of firms manufacture radio and television receivers and electronic equipment. The shipbuilding yards at Whyalla are the largest and most modern in Australia.

External Trade.—In the early 1960s the total value of South Australia's exports averaged about £A100,000,000 annually. Among the chief exports were wool, lead, wheat, barley, and ores and concentrates. During the same period the total value of imports was about £A60,000,000. Imports included machinery, motor vehicles, electrical equipment, and textile piece goods. (Though these figures are given in £A, Australia adopted a decimal system based on the dollar in 1966.)

Transport and Communications.—There are nearly 4,000 mi. of railway in South Australia, carrying about 15,000,000 passengers and 4,500,000 tons of freight annually. The state has about 87,000 mi. of road, of which about 6,400 mi. is hard surfaced. The cost of building and maintenance of roads is shared between the state and federal governments and the local councils. South Australia possesses several large harbours, the main one being Port Adelaide. Many ports serve small vessels, and there is a considerable coastal trade. In the early 1960s there were nearly 30 airfields in the state and 16 scheduled airline services carrying about 450,000 passengers annually. There were also about 200,000 telephones and 16 radio and 3 television stations.

Bibliography.—The most complete work on South Australia is *The Centenary History of South Australia*, prepared by the Royal Geographical Society of Australasia, South Australian branch (1936). *The Proceedings of the South Australian Royal Geographical Society* (1885–) contain many valuable studies. *See* also E. Hodder, *The History of South Australia from Its Foundation to the Year of Its Jubilee*, 2 vol. (1894); A. Grenfell Price, *The Foundation and Settlement of South Australia, 1829–1845* (1924); C. E. Fenner, *South Australia, a Geographical Study* (1931); D. H. Pike, *Paradise of Dissent: South Australia, 1829–1857* (1957); G. D. Coombe, *Responsible Government in South Australia* (1957); R. J. Best (ed.), *Introducing South Australia* (1958); Commonwealth Bureau of Census and Statistics, *Official Year Book of the Commonwealth of Australia* (annually).

SOUTH BEND, a city of northern Indiana, U.S., the seat of St. Joseph County, is 90 mi. (145 km.) E of Chicago on the south bend of the St. Joseph River, where it turns northward to Lake Michigan. The locale was visited by Robert de la Salle in 1679; the American Fur Company in 1820 and Alexis Coquillard in 1823 established fur-trading posts at the site. South Bend was platted in 1831, incorporated in 1835, and chartered in 1865.

The population of the city in 1960 was 132,445, that of the standard metropolitan statistical area (St. Joseph and Marshall counties) 271,057. (For comparative population figures *see* table in Indiana: *Population*.)

South Bend's industry is diversified, including manufacture of automobile and truck parts, aviation equipment, guided missiles, farm machinery, tools and dies, clothing, toys, baits and fishing rods, bearings, wallpaper, elastic and surgical goods.

The pioneer industries of South Bend were the Studebaker Brothers Manufacturing Company, the Oliver Chilled Plow Works, and the Singer Sewing Machine Company cabinet works. Studebaker began as a family-operated wagon-building business in 1852, and for 111 years it produced Studebaker wagons and then automobiles in South Bend. Studebaker made its first electric automobile in 1902 and its first gasoline model in 1904; wagon manufacture continued until 1920. It consolidated with the Packard Motor Car Company in 1954 and after 1960 diversified into various nonrelated manufacturing fields. By 1963 only the acquired industries consistently showed profits, and the company shifted all automobile production to its facility in Hamilton, Ont. Corporate offices remained in South Bend, but thousands of hourly rated workers left the city; others were absorbed by the small industries which purchased parts of the Studebaker plant. Readjustment for Studebaker workers was aided by a federal program of retraining the unemployed.

The Singer Company ended its cabinet production in South Bend in 1955. The plant location in 1868 had been determined by the availability of the northern Indiana hardwood forests. By 1901 it was the largest and finest cabinet factory in the world, with an employment peak of 3,000 in 1914. When it closed to move closer to lumber supplies, it was employing 1,200 men.

In 1960 the third of the early South Bend industrial giants underwent change when the Oliver Corporation became a wholly owned subsidiary of the White Motor Company. Oliver began manufacturing plows in 1855. In 1929 it incorporated with other plow manufacturers to broaden its line of farm implements. During the late 1950s much of its manufacturing was shifted from South Bend to other plants. By 1965 only 700 men were employed in the South Bend plant, most of them skilled workers.

About 45% of the South Bend working force is employed in manufacturing industries and 25% in transportation equipment fields. The city is surrounded by rich peppermint-growing muck which also produces potatoes, onions, and truck produce.

To the immediate north of South Bend lie two nationally known Roman Catholic educational institutions, St. Mary's College and the University of Notre Dame. Notre Dame, established in 1842 by Edward Sorin (*q.v.*), has a substantial academic reputation in the natural sciences. Its world-renowned Lobund Germfree Life Laboratory (*see* Germ-Free Life), its unsurpassed football teams, and its famous "gold dome" on the administration building are hallmarks of the university. St. Mary's, a small liberal arts college for women, chartered in 1851, is the mother house of the Sisters of the Holy Cross. South Bend also has an extension centre of Indiana University. Other community cultural programs are provided by the South Bend Symphony Orchestra, the Presbyterian Players, the South Bend Art Association, the Northern Indiana Historical Society, and the public library. South Bend lies near many small lakes and the Lake Michigan resort area. (J. J. D.)

SOUTH CAROLINA, popularly called the "Palmetto state," is an Atlantic coast state of the United States, one of the original 13. The eighth state to ratify the constitution, it entered the union on May 23, 1788. It is bordered on the north by North Carolina, on the south and west by Georgia and on the east by the Atlantic ocean. Its area is 31,055 sq.mi. (80,433 sq.km.), of which 783 sq.mi. (2,028 sq.km.) are water; in size it ranks 40th among the states. The South Carolina state flag has a blue field in the centre of which is represented a palmetto tree and in the upper corner of which, next to the staff, is a crescent. The state flower is the yellow or Carolina jessamine, the state tree the cabbage palmetto, the state bird the Carolina wren, the state song "Carolina." The capital is at Columbia (*q.v.*).

PHYSICAL GEOGRAPHY

Physical Features.—South Carolina (lying between the extremes of approximately 32° 4′ and 35° 12′ N. latitude and 78° 31′ and 83° 23′ W. longitude) is mainly in the coastal plain and Piedmont plateau regions, but in the northwest it extends slightly into the Appalachian mountain region. Locally the coastal plain region is known as the low country, and the Piedmont plateau and Appalachian mountain regions are called the upcountry. The coast is low, and islands increase in size and number toward the Georgia border. For about 10 mi. inland the coastal plain is occupied largely by salt marshes. Although continuing flat, the surface rises at the rate of approximately 2 ft. per mile for 50 mi. or more. Parts of the Blue ridge (*q.v.*) rise abruptly from the foothills to 3,425 ft. (1,044 m.) in Mt. Pinnacle, 3,208 ft. (978 m.) in Caesar's Head and 3,124 ft. (952 m.) in Table Rock. The highest point in the state is Sassafras mountain (3,560 ft. [1,085 m.]) in the Blue ridge and on the North Carolina state line. The mean elevation of the state is about 350 ft. (107 m.).

The principal rivers rise in the Appalachian mountains and flow southeast into the Atlantic ocean. Santee river is formed by the confluence of the Wateree (known above Wateree creek north of Camden as the Catawba; *see* Santee-Wateree-Catawba River System) and the Congaree, which is in turn formed by the Broad

and the Saluda. The basin of this system embraces about one-half the area of the state. In the northeast the Waccamaw and the Pee Dee and its tributaries—the Little Pee Dee and Lynches—are wholly within the coastal plain, but the main stream of the Pee Dee is a continuation below the fall line of the Yadkin river which rises in the mountains of North Carolina (*q.v.*). The Edisto is the principal stream in the southeast.

In the Piedmont plateau there are rapids in the rivers, but in the coastal plain the current becomes sluggish, and in time of high water the rivers spread over wide areas.

Climate.—Along the coast the climate is mild and equable. At Charleston, the mean winter temperature is 51° F. (10.6° C.), the mean summer temperature 80° (26.7°), the mean annual temperature 66° (19°) and the range of extremes from 104° to 7° (40° to −14°). For the state the mean temperature is about 63° (18°). In nearly all sections January is the coldest month and July the warmest. The mean annual rainfall for the state is about 47.75 in. (1,210 mm.) and its distribution is excellent, 17 in. (430 mm.) falling during the summer. Snow is uncommon in the southeast, but elsewhere there may be several inches, occasionally more than a foot.

The frost-free season ranges from 245 days on the coast to 204 days on the uplands. Tornadoes sometimes occur in the west, and the coast suffers from hurricanes.

Soil.—In general the soils of the Piedmont plateau are such as have been formed by the disintegration of the underlying rocks. These consist mostly of granite and gneiss, but in the north-central section there is trap and in the southeast section some slate. On the Piedmont plateau the subsoil is a reddish or yellowish clay. In the upper section of the coastal plain the soil is for the most part a loose sand, but near the coast it becomes more fertile, much being underlain by marl.

Vegetation.—Palmettos grow on the coast but only artificially inland. For some distance from the coast there are magnolias, live oaks draped with long gray moss and reed-covered marshes. In the swamps are cypress, gum and bay trees.

In most of the uplands of the coastal plain the longleaf pine is predominant, but large water oaks and undergrowths of several other oaks and of hickories are not uncommon. On the Piedmont plateau and in some of the more hilly sections below the fall line there is some shortleaf pine, but most of the trees in these areas are hardwoods. Deciduous oaks are commonest, but beech, birch, ash, maple, black walnut, sycamore and yellow poplar also abound. On the mountains are oak, chestnut, laurel, white pine and hemlock. Among indigenous trees, shrubs and vines are the blackberry, grape, persimmon, plum, crab apple, hickory, chestnut and hazelnut.

Animal Life.—Because of temperate climate and good rainfall, South Carolina has a wide variety of wildlife. Hunting has long been a favourite sport of the residents of the state, and many out-of-state persons are attracted by it. A number of large hunting preserves and lodges are maintained, especially in the low country. A state wildlife resources commission maintains a conservation program and supervises hunting and fishing laws. The laws specify the following as game animals, and, except during the open season for hunting, generally protected: deer, fox, mink, muskrat, opossum, otter, rabbit, raccoon, skunk and squirrel. Hunters also find duck, geese, quail and wild turkey in the state.

Though a relatively small state, South Carolina has a variety of fish, ranging from game fish in the offshore waters to trout in the northwestern mountains. The commonest fresh-water game fish are largemouth bass, white bass, bluegill, crappie, jackfish or pickerel, yellow perch and redbreast sunfish. Salt-water species found close to shore and in the inlets include channel bass, croaker, flounder, spot, weakfish and whiting. Farther offshore are amberjack, barracuda, blackfish, bluefish, grouper, mackerel, snapper and tarpon.

Parks, Historic Sites and Recreation.—The state maintains 27 state parks, many of which include facilities for boating and swimming as well as camping. Resorts and vacation places attract both South Carolinians and others in all seasons, especially to the mountains and seashore. Much of the coast of the state is marked by a strand and beaches that draw thousands every summer. An abundance of woods and waters is accompanied by a climate that permits year-round activities in most recreational pursuits.

Historic sites dating from days of Spanish and French exploration are to be found throughout the state. Many battles of the American Revolution and the Civil War took place in the state. Of special historical interest is Charleston (*q.v.*), site of the first permanent settlement and a city that still maintains much of its ante-bellum charm and character along with scores of historic landmarks and structures.

HISTORY

The history of South Carolina may be divided into the periods of discovery and exploration (1521–1670), proprietary rule (1670–1719), royal rule (1720–75) and statehood (from 1776).

The first Europeans to visit the coast were a party of Spaniards from Santo Domingo (Hispaniola) in 1521. The first settlement, most probably at Winyah Bay, was made by Spaniards under Lucas Vazquez de Ayllón in 1526, but after a few months it was abandoned. The Spaniards, again settling in 1566, maintained a fort on Parris Island for about 20 years. In the meantime (1562) French Protestants under Jean Ribault made an unsuccessful attempt to establish a colony on Parris Island (*see* PORT ROYAL). In 1629 Charles I granted to his attorney general, Sir Robert Heath, all the territory lying between the 31st and 36th parallels and extending through from sea to sea, but no settlement was made, and in 1663 the same territory was granted to the earl of Clarendon and seven other favourites of Charles II. A second charter in 1665 extended the limits to 29° and 36° 30′. The proprietors were to legislate for the province "by and with the advice, assent and approbation of the freemen." They were empowered, though not required, to grant religious freedom to Dissenters. Circulars were issued in 1663 and 1665 offering most liberal terms to prospective colonists. In the fundamental constitutions adopted by the proprietary board in 1669, John Locke and Lord Ashley prepared for the province an elaborate feudal system of government that would have been obsolete even in Europe. The colonial assembly refused (as the charter gave it the right to do) to adopt them. They were, nevertheless, an element in arousing the feeling of discontent among the colonists which culminated in the overthrow of proprietary rule, and they encouraged the large plantation system which constituted the foundation of the slaveholding aristocracy.

Proprietary Period.—The first permanent English settlement was made in April 1670 at Albemarle point on the west bank of the Ashley river, but as the situation proved unfavourable the government and most of the people moved over in 1680 to the point between the Ashley and Cooper rivers, the site of the present city of Charleston. The area of settlement was gradually extended along the coast in both directions, but did not penetrate far into the interior until after 1730. There were many English from Barbados and French Protestants, both of whom strongly influenced the history of the province.

South Carolina's political history during the colonial era is the story of a struggle between popular and prerogative interests, between the people and the lords proprietor, then, later, between the people and the crown. From 1670 to 1700 the principal questions at issue were the refusal of the settlers to subscribe to the numerous editions of the fundamental constitutions and disputes over the collection of quitrents. Concessions were finally made which brought the government more directly under popular control. In 1693 the commons house elected by the people secured the privilege of initiating legislation. The truce was followed by a controversy between Anglicans and Dissenters. A test act requiring members of the assembly to conform to the Church of England and to take the Sacrament of the Eucharist according to the rites and usages of that church (1704) was defeated only through the intervention of the Whig house of lords in England. By an act of Nov. 30, 1706, which remained in force until 1778, the Church of England was made the established religion. After a few years of peace and prosperity, the proprietors, acting on the advice of Chief Justice Nicholas Trott, adopted a reaction-

ary policy, vetoed several popular laws and could not give aid in the desperate 1715 Indian war. In 1719 the people rebelled, overthrew the existing government and elected their leader, James Moore, governor.

Royal Rule.—The result of the revolution was accepted in England, and the province at once came under royal control, although the rights of the proprietors were not extinguished by purchase until 1729.

Theoretically South Carolina and North Carolina constituted a single province, but, as the settlements were far apart, their governments were always separate. Until 1691 each had its own governor. From 1691 to 1712 there was usually a governor at Charleston and a deputy for the northern settlements, and after 1712 there were again separate governors. An order of 1730 for a survey of part of the boundary was carried out in 1735, but the definition of the whole boundary was not completed until 1815.

The period 1725–75 was a period of great prosperity, based upon the trade in pelts (mainly deerskins) and more permanently on the rapidly expanding production of rice and indigo. The southern colonies' Indian trade centred mainly in Charleston. This, and a rich agriculture and the large commercial business to serve them, supplied the economic basis of a coast country society of notable intelligence and culture. One of the earliest theatres in America, musical culture, libraries and the education of a large number of youths in England gave the society around Charleston a tone and finish at that time rare in the new world.

Passing under the royal government did not check the encroachments upon the governor and council by the commons house of assembly, which defiantly announced the powers of the British commons as its model. By 1760 the council had almost ceased to exercise any real control over legislation. It rarely initiated or amended a bill and never attempted to change a money bill without incurring violent denunciation from the popular house and paralyzing legislative action, once for years.

The province was unconsciously preparing for independence. Though measures of the British government after 1763 were not especially oppressive to the province, the people were too long accustomed to having their own way. They had, especially in the bitter dispute over the Wilkes fund (1769–75), involving the right of the commons alone to control finance, developed too fully a sense of general American and even British freedom to submit to measures which they regarded as subversive of the principles of liberty.

Delegates were sent to the Stamp Act congress (1765) and to the Continental congresses (1774 and 1775). A council of safety appointed by an extralegal provincial congress virtually took over the government in June 1775. Royal administration ended when, on Sept. 15, the governor dissolved the assembly and fled.

Revolution.—Wars with the Spanish in 1686, 1702–04 and 1740, with the Spanish and French in 1706, with pirates in 1718, with the Yamasee Indians in 1715 and the Cherokees in 1760–61, with aid from British troops only in 1760–61, and a slave rising in 1739 had accustomed the people to arms. The state suffered severely during the American Revolution both from British troops and from the presence of numerous loyalists. A British fleet attempting to capture Charleston was repulsed by Ft. Moultrie, June 28, 1776. Calm prevailed until Gen. Sir Henry Clinton returned in 1780 with an overwhelming force and obtained the surrender of the city from Gen. Benjamin Lincoln on May 12.

Completely overrun, the state experienced two years of fighting involving more battles, though most of them small, than occurred in any other state. A continental army under Gen. Nathanael Greene, assisted by state troops under Thomas Sumter, Francis Marion, Andrew Pickens and others, slowly drove the British back into Charleston and wrecked the plan of British troops from the south to join those from the north to crush Washington. The chief Revolutionary War battles fought in the state were at Ft. Moultrie, the siege of Charleston (March 12–May 12, 1780), Camden (Aug. 16, 1780), King's mountain (Oct. 7, 1780), Cowpens (Jan. 17, 1781), Hobkirk's hill (April 25, 1781) and Eutaw Springs (Sept. 8, 1781).

Early 19th Century.—The period following the Revolutionary War witnessed an ambitious program of transportation development. The Santee canal, connecting Charleston with the whole Santee-Wateree-Broad-Saluda River system, was opened in 1800. Highway building followed. The latter was dropped, however, and the canal was ruined by railroad development. The South Carolina railroad, 136 mi. from Charleston to Hamburg opposite Augusta, Ga., when completed in 1833, was the longest railroad in the world.

The early state period was characterized by a bitter struggle between the older low country and the newer upcountry, the latter settled largely by Scotch-Irish coming down the Piedmont belt from Pennsylvania, Virginia and North Carolina. In 1786 it was necessary, to allay discontent, to consent to the removal of the capital to a newly located site to be called Columbia. Although removal took place in 1790, some state officers until 1865 kept offices both in Columbia and Charleston and the supreme court met in each city to hear appeals from the two sections. The upcountry (then comprising a larger area than now thus designated), containing four-fifths of the white population and one-fifth the wealth, in 1808, with the help of a liberal low country minority led by Joseph Alston, secured a constitutional amendment apportioning one senator to each county and representatives to each county in proportion equally to white population and wealth. This left the control of the upper house to the low country and that of the lower house to the upcountry. Manhood suffrage followed in 1810. The low country's fear for its slave interests was allayed as slavery, fostered by the increasing

THE GRANGER COLLECTION

LINE ENGRAVING OF CHARLESTON HARBOUR, 1739

Charleston, the earliest permanent English settlement in South Carolina, is still the state's chief port

importance of cotton, spread up the state.

The South Carolina college was chartered in 1801 largely to allay sectional antagonisms. The necessity of standing unitedly against antislavery and later radical Reconstruction agitation from the North prevented the masses from forcing democratic changes until late in the 19th century.

Northern antislavery agitation and the adoption of a tariff harmful to southern agriculture united both sections in the passage of the ordinance of nullification, Nov. 24, 1832, forbidding the execution of the tariff in South Carolina (*see* NULLIFICATION). The readiness of a powerful minority to assist Pres. Andrew Jackson, combined with a reduction of the tariff, operated to deter the majority from forcing the issue to armed conflict, but left a bitterness within the state that disappeared only after 1840 in the face of a graver danger from outside.

After a serious slave conspiracy in 1822 and northern abolitionism in the 1830s, the slave code was severely revised (1840–44), even to forbidding the sending of a slave to freedom anywhere in the world. The years 1847–52 saw most of the people of South Carolina deterred from secession only because of lack of co-operation from other southern states. After 1828 Virginia's southern leadership was superseded by the more uncompromising leadership of South Carolina under John C. Calhoun. South Carolina was the first state to secede, its ordinance of Dec. 20, 1860, being almost unanimously approved by its citizens.

Civil War and Reconstruction.—With a white population of 291,300, the state put into the field an estimated 62,838 effectives,

BRUCE ROBERTS FROM RAPHO GUILLUMETTE

PARROTT GUNS AT FT. SUMTER IN CHARLESTON HARBOUR, THE SCENE OF THE FIRST ENGAGEMENT OF THE AMERICAN CIVIL WAR, APRIL 12–14, 1861

of whom 22% were killed or died in prison. Gen. William T. Sherman's march across the state in 1865 was accompanied by enormous destruction, including the burning of Columbia.

The misfortunes of war were more easily borne than the humiliation of Reconstruction. Under Pres. Andrew Johnson's guidance, the white population elected officers who were soon ejected under the congressional plan of Reconstruction, disfranchising many whites and transferring power to unprepared Negroes, northern adventurers (carpetbaggers) and white loyalists of the South (scalawags) joining them. In the spring of 1868 the state was re-admitted to the union, and entered upon a period of eight years of crime and corruption. Much legislation was by bribery. Stealing extended from large blocks of state property to the price of a politician's whisky. Two hundred trial justices were said to be unable to read. Daniel H. Chamberlain, able carpetbagger and would-be reformer of his own party (governor, 1874–76), declared in 1901 that if he had been re-elected in 1876 his party, even with white assistance, could not have given government "fit to be endured." The most urgent pleas on a nonpartisan basis failing to draw the least sympathy in Washington, the whites in 1876, by combined fraud, intimidation and persuasion of Negroes, elected Gen. Wade Hampton (1818–1902) governor by a narrow majority. Pres. Rutherford B. Hayes's withdrawal of troops in March 1877 marked the collapse of "radical" rule.

Political Developments.—In 1878–80, under the leadership of M. W. Gary (1831–81), the old conflict between upcountry and low country became a fight mainly between the poorer masses and the propertied classes.

The triumph of the former under Benjamin R. Tillman (governor, 1890–94; U.S. senator, 1895–1918), prominent farmers' movement leader, was facilitated by acute agricultural distress. Tillman's victory had come in the state Democratic convention, which had been captured by his agrarian rebels. In the subsequent general election, Col. A. C. Haskell, a conservative representing the Bourbon class who had ruled the state since 1876, bolted the party and campaigned against Tillman, making his appeals to both conservatives and Negroes. His efforts failed and served only to embitter feelings among the whites. The farmers', or more broadly "reform," movement was marked by the establishment of Clemson Agricultural college (1889), the chartering of Winthrop college for women (1886), the dispensary system of state liquor monopoly (later abandoned because of corruption and failure to restrain intemperance) and the work of the constitutional convention of 1895 disfranchising so far as possible the Negro. Direct primary elections, long in use in most of the counties, beginning in some in 1878, were adopted in 1896 for naming the U.S. senators, governor and state officers.

State politics after 1890 presented a strange combination of rancorous personal politics, mass conservatism and dislike for "aristocratic" influence. Class feeling was strongly manifested in the campaigns of Coleman L. Blease (governor, 1911–15). R. I. Manning's administrations (1915–19) were notable for progressive legislation. Factionalism subsiding, Blease was in 1924 elected senator, after having been badly defeated in 1918 on a platform condemning U.S. participation in World War I.

Agriculture and banking suffered severely in the deflation of 1920–21, and all business still more from 1929 to 1937. North and South Carolina were the only states voting against the repeal of national prohibition in 1933. In 1935 Gov. O. D. Johnston climaxed his long hostility to the highway department and its chief commissioner, Ben M. Sawyer, by military seizure of the department until condemned by both legislature and supreme court. Public esteem for the construction by the department seemed justified by the failure to discover any wrong. Extensive violent strikes in 1935–36 caused a conservative reaction. Pres. Franklin D. Roosevelt's attempt to have Sen. E. D. Smith defeated resulted in Smith's overwhelming re-election in 1938, although the state supported Roosevelt's general policies.

From 1876 almost the entire white population was Democratic, partly from historical reasons and partly because of the conviction that union under the only national party that had defended them against Negro rule in the past was necessary for the maintenance of white supremacy. In 1948 the state bolted the Democratic party, casting its eight electoral votes for Gov. J. Strom Thurmond, of the dissident States' Rights Democratic party. In 1952, 1956 and 1960 the state gave its strongest support since Reconstruction to the Republican presidential candidates, and in 1964 cast its electoral votes for Republican Barry Goldwater.

In 1950 new election laws were passed controlling general elections and providing the secret (Australian) ballot in general elections for the first time in the history of the state. Conduct of party primaries was again put under state control (after a 1944 ruling by the U.S. supreme court that had opened primaries to Negroes if conducted under state authority, the legislature had repealed all primary election laws to make primaries voluntary and not subject to federal interference). In 1951 the state abolished the poll tax as a voting requirement and also undertook to curb activity of the Ku Klux Klan.

Economic Changes.—As other parts of the south, the state began an industrial revolution in the 1940s, to a large extent attributable to expansion and building related to World War II. This trend in South Carolina was accelerated following the war and was officially encouraged by the State Development board (established 1945). Changing the character of the state has been the growing diversification of its industry. Considerable growth occurred after 1939 in clothing, furniture, meat packing and the

chemical and paper and pulp industries. The U.S. Atomic Energy commission also established its huge Savannah River plant in the state. (*See* also *The Economy*, below.) Accompanying the 20th-century industrial revolution was a relative decline of the agriculture which once dominated the state's economy (*see* also *Agriculture*, below). Despite the rapid expansion of industry the large number of marginal agricultural workers kept the per capita income of the state low (about $1,600 in the 1960s as compared with the U.S. average of $2,400).

GOVERNMENT

South Carolina was governed from 1670 to 1719 under the provincial charter of 1665, from 1719 to 1775 under commissions and instructions from the crown and from 1776 under constitutions of 1776, 1778, 1790, 1865, 1868 and 1895. An amendment to the constitution may be proposed in either house of the legislature. If approved by two-thirds of the members elected to each it must be submitted to the people at the next election for members of the house of representatives. If it is approved by a majority of those voting upon it and subsequently by a majority vote in each house of the general assembly chosen at that election, it becomes a part of the constitution. A convention to revise the constitution may be called by a two-thirds vote in each house ratified by a majority of those voting for representatives at the next election.

A voter must be 21 years old, a resident of the state two years, of the county one year and of the voting precinct four months; and must obtain a certificate of registration conditioned on showing that he or she is able to read and write the constitution, or the past year paid taxes on property assessed at $300 or more. Paupers, idiots, the insane, prisoners and persons ever convicted of certain crimes, unless pardoned, are disfranchised. The application of the literacy test or other restrictions in such a manner as to prevent Negroes from registering or voting was prohibited by the Voting Rights act of 1965.

Until the slow emergence of a two-party system in the 1960s, the Democratic nomination was equivalent to election. Voting in the Democratic primary was confined to whites without other qualification than age and residence until federal courts in 1948 ordered Negroes admitted to party membership. An increasing number of Negroes voted after that date, with voting qualifications the same after 1950 in both primaries and general election.

Executive.—Constitutional amendments changed the terms of the governor and other state officers from two to four years, beginning with those elected in 1926. The governor may not succeed himself. He may veto "any one or more of the items or sections contained in any bill," but may be overruled by a two-thirds majority of those voting in each house. In practice the item veto has been used only for appropriation bills. The governor cannot grant pardons except on the recommendation of the pardon board, but he may commute a death sentence to life imprisonment.

Legislative.—The general assembly, meeting annually, is composed of the senate (one member from each of the 46 counties elected for four years) and the house of representatives (124 members elected for two years from the counties in proportion to population). The state elects six congressmen.

Judiciary.—The 5 supreme court judges and the 14 circuit court judges are elected by the legislature for ten and four years respectively. Magistrates (justices of the peace) are appointed by the governor with senate confirmation, although the recommendation of the senator from the county or of the primary election practically determines the selection.

In a number of counties, a county court (with a judge usually elected) disposes of a large part of the lesser civil and criminal cases elsewhere burdening the state circuit courts. Special juvenile courts have been established in some counties; elsewhere the probate judge has this duty. The state is divided into two federal court districts.

Local Government.—The unit of local government is the county. Counties are divided into townships, which have no governments and exist largely for the assessment of taxes. Although the forms of municipal government are provided under general statutes and enjoy certain constitutional rights, they are considered subject to state legislative authority. New industries are encouraged to locate in the state by exemptions from certain municipal and county taxes under conditions set by the state constitution and statutes.

The county is administered by a commission, almost always popularly elected. Road or hospital commissions, etc., are frequently appointed by the governor, usually upon recommendation of the county legislative delegation. Most of the county officers are elected, with the exception of the auditor and treasurer, who are appointed by the governor with senate confirmation; however, the governor almost always names the successful primary election candidates without question.

Since there is no legislative body on the county level, the state legislature is oppressed with a mass of local legislation. In actual practice it enacts without question whatever the senator and representatives of the county concerned agree upon. The delegation thus forms in effect a county legislature. The senator of each county, by controlling action in the senate, exercises an enormous power and in effect has a veto over any legislation concerning his county.

Finances.—The state tax commission, created in 1915, supervises all tax administration and directly administers those taxes from which most of the state revenue is derived, such as taxes on incomes, gasoline, retail sales, soft drinks, beer and liquor, electric power, corporations and business. There exists in practice a considerable separation of state and local tax sources, the local governments depending mainly on the general property tax; however, the counties receive a share of state gasoline and income taxes, and both county and municipality share the state tax on alcoholic beverages.

POPULATION

The population of South Carolina in 1790 was 249,073; in 1840 it was 594,398; in 1880, 995,577; in 1910, 1,515,400; in 1940, 1,899,804; in 1950, 2,117,027; and in 1960, 2,382,594. The 1960 figure represents an increase of 12.5% over the population in 1950. The population per square mile in 1960 was 78.7, as compared with

*Populations are reported as constituted at date of each census. †Name changed from Brookland in 1938.
Note: Dash indicates place did not exist during reported census, or data not available.

68.2 in 1950 and with 49.6 for the United States in 1960.

Of the 1960 population, 739,300 or 31% lived in incorporated places of 2,500 or more, as compared with 28.8% in 1950. The entire urban population amounted to 981,386, or 41.2% of the state total. The state has three standard metropolitan statistical areas, which are Charleston, Columbia and Greenville and part of a fourth (Augusta, Ga.). These areas had a total population of 768,024, or 32.2% of the total population of the state in 1960.

The number of households in 1960 was about 604,000, as compared with 515,000 in 1950. The average population per household had declined from 4.0 in 1950 to 3.8 in 1960.

The population of the state was distributed by colour and nativity in 1960 as follows: 64.7% native white; 0.4% foreign-born white; and 34.9% nonwhite, practically all Negro. There were 100.1 males per 100 females in the native white population and 92.9 in the Negro population; 6.2% of the population was 65 years old or over; and 66.3% of the population 14 years old and over was in the labour force. Of the total number of employed, 11.7% were engaged in agriculture, 6.4% in constuction, 32.0% in manufacturing and 2.3% in transportation.

EDUCATION

Public Schools.—As early as 1710 the state made meagre provision for the education of indigent children, and in 1811 an effort was made to inaugurate a genuine public school system. Because of small appropriations and a law that paupers be given first preference, this system proved very inadequate and most education continued to be by private schools and academies in the antebellum period.

The modern free school system was established in 1868. The educational system is under the supervision of a state superintendent of education, with the assistance of a board composed of the governor, the superintendent of education and seven other persons appointed by the governor. State support and regulation of high schools were greatly increased in 1907.

In 1951 Gov. James F. Byrnes successfully sponsored a long-range expansion program designed to improve and equalize physical facilities for white and Negro schools. State bond issues up to $75,000,000 (later increased) were authorized and a 3% retail sales tax earmarked for education was adopted. Prior to this, white children, who in 1950 constituted 55% of the school population, had occupied school property constituting 71.3% of the total value; in 1950 about 67.5% of new construction had been for white schools. Both this ratio and the total expenditure were altered by the 1951 reform efforts. In the first year of the program 78% of the funds for school construction was spent on Negro schools. The value of school property increased from $41,600,760 in 1930 to $90,720,547 in 1950, and to more than $400,000,000 in the 1960s. Annual per pupil cost to the state increased from $35.82 in 1930 to more than $200 in the mid 1960s. In the 1960s per capita average spending for education was about $165 a year in state and local money, in comparison with the national average of a little over $150. While it ranked 49th among the states in per capita income of its inhabitants, South Carolina ranked 29th among all states in the amount contributed toward public education, and was near the top in the percentage of total expenditures devoted to education.

The 1954 decision of the U.S. supreme court holding compulsory racial segregation in public schools unconstitutional centred political activity and public interest on the racial issue. The state constitution was immediately amended to remove the requirement of state support for schools. In 1955 the legislature repealed the compulsory attendance law and the law regulating school terms. Local school boards of trustees were given increased authority and freedom, including the exclusive authority to operate or not operate schools. Beginning in 1963, policy showed signs of change as Negroes were admitted peacefully to the public schools in Charleston and to two state-supported colleges, Clemson and the University of South Carolina. Accompanying these changes were numerous instances of quiet desegregation of various public accommodations and businesses.

Enrollment in public elementary schools at that time was about 406,000, of whom more than 225,500 were white and 180,000 Negro; in high schools there were about 234,000, including 146,000 white and 87,000 Negro. (Negro high school enrollment in 1930 had been only 35,000.)

Higher Education: *State Institutions.*—The state government supports several institutions of higher learning, chief among which is the University of South Carolina at Columbia. The university, chartered as South Carolina college in 1801 and opened for instruction in 1805, comprises schools of arts and sciences, business administration, education, engineering, journalism, law, nursing and pharmacy. It also has regional campuses at Aiken, Beaufort, Conway, Florence, Lancaster, and Union. By the 1960s the university enrolled about 7,000 students annually.

Clemson university, formerly agricultural college, at Clemson (incorporated 1889) is a university and land-grant college, with schools of agriculture, architecture, engineering and textiles, arts and sciences, and graduate school. Winthrop college at Rock Hill (established 1886) is a state college of liberal arts for women, specializing in teacher training. At Charleston is located the Citadel, the Military College of South Carolina (1842), one of the few state-supported military colleges. The South Carolina State college at Orangeburg (1896), for Negroes, has schools of arts and sciences, agriculture and home economics, education, industrial education, graduate studies, and law, and graduate extension and summer schools.

Private Institutions.—Among the private institutions are Columbia college, for women, at Columbia (Methodist, 1854); Erskine college, at Due West (Presbyterian, 1839); Furman university, at Greenville (Baptist, 1826); Newberry college, at Newberry (Lutheran, 1856); Presbyterian college, at Clinton (Presbyterian, 1880); Central Wesleyan college, at Central (Wesleyan Methodist, 1906); Wofford College, for men, at Spartanburg (Methodist, 1854). There are also several nondenominational colleges: Bob Jones university, at Greenville (1927); Coker college, for women, at Hartsville (1908); College of Charleston (1770); Converse college, for women, at Spartanburg (1889); Lander college, at Greenwood (1872); and Limestone college, for women, at Gaffney (1845).

In addition to the state college, private colleges established for Negroes, included Allen university, at Columbia (African Methodist, 1870); Benedict college, at Columbia (Baptist, 1870); Claflin university, at Orangeburg (Methodist, 1869); and Morris college, at Sumter (Baptist, 1908).

HEALTH, WELFARE AND CORRECTIONS

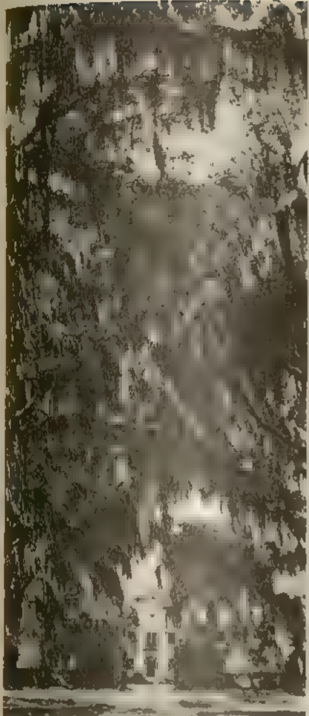
The state has maintained a state board of health since 1879, and beginning in the 1880s similar agencies were established on the municipal level and later by counties. The state board conducts programs for the control of preventable diseases and for maternal and child care. Its program was expanded considerably following passage of the Social Security act in 1935. The state also maintains a mental health commission. Most mental patients are treated at the state hospital, Columbia, although there are four other smaller institutions for such care as well as five mental health clinics.

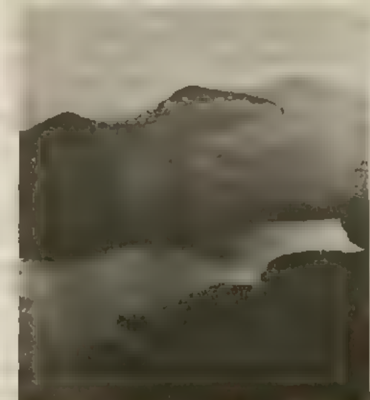
The state department of public welfare (established 1937) is concerned mainly with dependent children, the blind and the aged. South Carolina in 1964 inaugurated a special antipoverty program to reduce illiteracy and unemployment, becoming the first state to use federal funds made available for this purpose under the Manpower Development and Training act (1962).

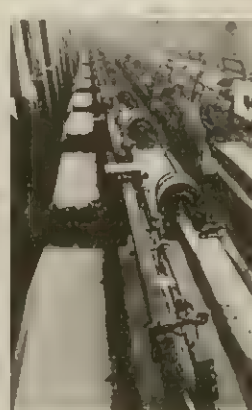
The state and counties share in maintaining penal institutions for convicted criminals. The state maintains a penitentiary, reformatories and industrial training schools for delinquent minors.

THE ECONOMY

Agriculture.—South Carolina's farm products are normally valued at much less than its factory output. Thus, in the second half of the 20th century, the value of manufactures was over six times greater than the gross income from agriculture. The average size of farms increased, mechanization was widely adopted and farmers generally shared in prosperity. From 1920 through 1950,







(LEFT, CENTRE) TOM HOLLYMAN—PHOTO RESEARCHERS, INC.; (TOP) FREDERICK C. BALDWIN—PHOTO RESEARCHERS, INC.; (RIGHT) BRUCE ROBERTS FROM RAPHO GUILLUMETTE

(Left) Live oaks, festooned with Spanish moss, at Boone Hall plantation near Charleston; (top) small boy fishing on the Edisto river, principal stream of southeastern South Carolina; (centre) Table Rock and lake in the Blue Ridge Mountains, northern South Carolina; (right) spinning room in a Piedmont cotton mill: South Carolina is the largest producer of textiles in the U.S.

the number of farms had declined by more than 25% and the farm population by more than one-third. South Carolina agriculture, like industry, became more diversified in the 20th century. This was particularly noticeable in the case of cotton, which declined 68.6% in value during the period, and in that of peaches, production of which increased by 737.8%.

Total farm acreage harvested in the 1960s was about 2,500,000, in comparison with 4,000,000 in 1950. In the 1960s less than 30% of farm operators were tenants, as compared with 39% in 1954 and 65% in 1930.

Cotton, long dominant in agriculture in South Carolina, took second place to tobacco in crop value for the first time in 1955. In value of production in the 1960s, tobacco led, followed by cotton, soybeans, corn, peaches and hay. These six principal crops accounted for 90% of all crop income.

The coastal region, with a mild climate and a soil responding quickly to intensive cultivation, is especially suited to commercial truck farming. The chief products, exclusive of potatoes and sugarcane grown for sirup, are watermelons, cabbages, cucumbers, string beans, beets, asparagus, tomatoes and lettuce. Strawberries, dewberries, blackberries, figs and grapes add to the fruit wealth of the state.

Dairying and livestock industries were receiving much greater attention by the 1960s. Between 1920 and 1950 the value of cattle increased 62% while the value of hogs increased 27%. Leading livestock and products include poultry and eggs, meat animals and dairy products.

Forests.—Forests make up about 60% of the area of South Carolina, and timber resources are estimated at about 15,000,000,000 bd.ft. in softwoods and 10,700,000,000 bd.ft. in hardwoods. A great deal of emphasis has been placed on pulpwood production for use in the paper industry.

Minerals.—South Carolina's mining output is very small, amounting to 0.19% of the total mineral value of the United States. Chief minerals are kaolin (china clay), vermiculite (produced in substantial quantities in only one other state), stone, sand and gravel. The stone quarried is chiefly granite and granite-gneiss. High-grade granite, the Winnsboro Blue, is quarried in Fairfield county.

Manufactures.—An industrial revolution in South Carolina that began in the 1930s continued into the 1960s, considerably overshadowing agriculture. By the 1960s there were 2,500 manufacturing establishments (up 150% over 1936) employing 250,000 workers (up 100%), and annually producing goods worth $4,000,000,000 (up more than 1,000%). Besides new local industries, many manufacturing operations were moved to South Carolina, and many industries added new plants in the state. Older industries also undertook expansion. With 36% of the spindle hours in the nation, textiles dominate industry in the state (about 50% of total value added by manufacture) and make South Carolina the largest textile producer in the United States. In value added by manufacture, the leading industries of the state are textiles, chemicals, clothing and apparel, paper products, lumber and wood products, and tobacco products.

Textiles consume about 2,500,000 bales of cotton annually. Almost every grade of cotton cloth is produced, and there is also widespread use of synthetic materials, many of which are made in the state. Factors contributing to the rapid development of the cotton textile industry in South Carolina were a suitable climate, dependable labour and an abundance of cheap hydroelectric power. The Piedmont section has led in the textile industry, chief producing counties being Spartanburg, Greenville, Anderson, York, Kershaw and Greenwood.

Charleston and Richland counties are important for diversified industry. Industries showing the greatest growth between 1936 and the 1960s were clothing, furniture, meat packing and paper and pulp.

Hydroelectric development and new steam generating plants greatly aided industry and improved living conditions. Of the numerous hydroelectric installations the greatest is the publicly owned Santee-Cooper project, producing approximately 133,000 kw. Its two reservoirs (Lakes Marion and Moultrie) have a combined area of 160,000 ac. (64,800 ha.). The Clark Hill dam supplies the U.S. Atomic Energy commission's Savannah River plant in Aiken and Barnwell counties.

Lake Murray dam, about 10 mi. (16 km.) above Columbia on the Saluda river, 208 ft. (63 m.) high and 7,000 ft. (2,100 m.) long (one of the largest earth dams), forms a lake about 50,000 ac. (20,200 ha.) in area and develops 130,000 kw. The state's total installed generating capacity (both privately and publicly owned) is about 3,000,000 kw.

Transportation, Commerce and Communication.—Main-line railway mileage in South Carolina was reduced from 3,780 mi. (6,083 km.) at the end of 1930 to 3,250 mi. (5,230 km.) in the 1960s. During the same period there was a steady increase in the mileage of paved roads built by the state government. By the 1960s there were more than 30,000 mi. (48,000 km.) of state highways; the post-World War II period brought 15,000 mi. (24,000 km.) of paved secondary roads also.

Ocean traffic through Charleston (*q.v.*) and Georgetown expanded greatly after World War II, promoted by the State Ports authority, which began a large expansion of port facilities in 1958. Charleston ranked 15th among the nation's ports in the 1960s, and leads all South Atlantic ports in the dollar value of imports and exports.

SOUTH CHARLESTON, a city of West Virginia, U.S., across the Kanawha River from Charleston (*q.v.*), is an important chemical manufacturing centre. It was founded in 1916 and incorporated in 1917. Two chemical companies were established there in 1916, and a plant built in 1920 to manufacture antifreeze has become the city's largest single industry, employing over 10,000 workers and participating in the manufacture of about 450 articles. A U.S. naval ordnance plant in South Charleston from 1917 also stimulated the economy. In the heart of the city is an Indian mound 33 ft. (10 m.) in height and 550 ft. (168 m.) in circumference. In 1883 it was explored to a depth of 31 ft. by archaeologists under the direction of the Smithsonian Institution at Washington, D.C. For comparative population figures *see* table in WEST VIRGINIA: *Population*. (K. K. McC.)

SOUTHCOTT, JOANNA (1750–1814), English prophet, whose utterances, dated and sealed on the day she received them, were preserved in a box that, by her wish, was to be opened by 24 bishops a century after her death. The box has never been opened, though as late as 1935 a petition to do so, bearing nearly 29,000 signatures, was presented to the archbishop of Canterbury. Born in April 1750 at the East Devonshire village of Gittisham, Joanna worked as a maidservant and upholsterer and lived a conventionally normal life until, in 1792, her hand began to write automatically. The words were largely biblical, for she was a devout Anglican who also attended Methodist meetings. Assuming that the thoughts came from God, she had them printed. Seven disciples of Richard Brothers (*q.v.*) were impressed and brought her to London in 1802. Her main message was "Christ's Second Coming is nigh." She enrolled 40,000 disciples, including clergy. After puzzling much over the prophecy about the woman whose son was "to rule all the nations" (Rev. 12:5), she developed signs of pregnancy although elderly and chaste (1814). Prominent London doctors assured her that she had conceived a child, and she expected a virgin birth. The child was to be Shiloh, a name connected with an obscure biblical prophecy (Gen. 49:10). But on Dec. 16, 1814, her doctors found that every sign of her phantom pregnancy had vanished, and she died of unknown cause on Dec. 27.

See G. R. Balleine, *Past Finding Out* (1956). (G. R. B.)

SOUTH DAKOTA, popularly called the "Coyote" or "Sunshine state," is one of the north-central plains states of the United States, bordered on the north by North Dakota, east by Minnesota and Iowa, south by Nebraska and west by Wyoming and Montana. It is 372 mi. (599 km.) (east-west) by 204 mi. (328 km.), with an area of 77,047 sq.mi. (199,552 sq.km.), of which 669 sq.mi. (1,733 sq.km.) are covered by rivers and lakes; in size it ranks 16th among the states. Its name is taken from the Dakota or Sioux Indians. The geographical centre of the United States is in the northwestern part of the state. South Dakota was admitted to the union in 1889 as the 40th state. Its capital is at Pierre (*q.v.*). The state motto is "Under God the People Rule," the flower is the American pasqueflower, the bird, the ringnecked pheasant, the song (unofficial) "South Dakota." The state flag has a field of blue on which is represented a blazing sun in gold surrounded by the words "South Dakota the Sunshine State."

PHYSICAL GEOGRAPHY

Physical Features.—South Dakota (extreme points 42° 29′ and 45° 57′ N. lat. and 96° 26′ and 104° 3′ W. long.) has some of the features of regions that bound it: the mountains of Wyoming to the west, the lakes of Minnesota to the east and the rich corn lands of Iowa to the southeast. With its other border states, Nebraska and North Dakota, it is part of the continental Great Plains (*q.v.*), a land that rises gradually to the foothills of the Rockies, accompanied by a climatic change from humid to semiarid. The half of the state east of the Missouri, which originally flowed in the valley of the modern James river, was subjected to glacial action and is largely flat prairie. In the northeastern part of the state there are numerous glacial lakes. Oddly, the lowest point in the state, at the northeastern edge, is a continental divide. From this point waters flow northward to Hudson bay and southward into the Gulf of Mexico. Apart from this extreme corner, the entire state is drained by the Missouri river and its tributaries.

The Missouri, which bisects South Dakota north-south, flows through a veritable gorge except for a short stretch above Sioux City, Ia., at the southeastern corner of the state. The channel is 300 to 500 ft. below the bordering uplands, with the river plain seldom more than two miles and often less than one mile in width. This feature has made possible the location of four federal dams, primarily for hydroelectric power and flood control, along the South Dakota stretches of the Missouri. Total installed capacity is set at 1,232,000 kw. The dams form a series of lakes roughly equal in area to the state's natural water area.

The valley of the James river, on the other hand, averages 60 mi. in width, and the river drops only 100 ft. in its course from north to south across the state (east of the Missouri). The *coteaux* on either side of the James are largely undrained, reflecting their glacial history. The Big Sioux river is at the eastern edge of the state, where, for the last part of its course, it forms the state boundary.

The land west of the Missouri is largely rolling grassland, cut by a number of streams of considerable size. On either side of the White river are the Bad Lands (*q.v.*), the eroded sections of which, banded in soft colours and carved into unusual shapes, are interspersed with numerous well-grassed flat-topped tablelands.

From the James river to the Black hills at the western edge of the state the land rises gently from 2,000 ft. above sea level to 3,700 ft. This area is subject to recurrent periods of drought, the worst occurring in the early 1890s and in the 1930s.

The Black hills (*q.v.*) are actually well-eroded mountains, Harney peak (7,242 ft. [2,207 m.]) being the highest point in the United States east of the Rocky mountains. The region is virtually the only wooded section of the state and the source of a wide variety of minerals. There are three national forests in the western part of the state, covering nearly 2,000,000 ac.

Climate.—South Dakota straddles the 100th meridian, the usual dividing line between the arid and more humid sections of the United States. Rainfall is heaviest in the southeast, averaging 24 in., but tapers off to the west and north to a low of 14 in. Variability in the weather and a wide range of temperature help

to make the climate invigorating. Highest temperature recorded is 120° F.; the lowest −58°. Droughts of varying intensity marked the periods 1886–94, 1910–11, 1930–36 and the mid-1950s. It is estimated that much of the state receives less than 75% of its normal rainfall 20% of the time. The average snowfall is 36 in., ranging from 22 in. to about 59 in. Three-fourths of all precipitation occurs during the growing season. Contrary to popular belief, blizzards are not common. The severest storms on record are those of 1881 and 1949.

Soil.—Most of the eastern half of the state lies in the chernozem (black earth) belt of the Great Plains. The soil varies in depth from 18 to 28 in., is rich in lime and highly fertile. The chestnut soils of western and northwestern South Dakota range from 6 to 14 in. in depth and are generally fertile, but climatic factors limit their use. Soils in the Black hills are thin and vary widely in type. The parent materials of most soils in the state are soft rocks, loess, glacial till and alluvium. Clay and clay shale are important parent materials in the west-central section where gumbo soil or Pierre clay is found. Fringe areas on the northern and southern borders of the state have soils derived from sand.

Vegetation and Animal Life.—A wide diversity of trees is native to the eastern section, including elm, oak, box elder, cottonwood and hackberry. Small cedars are found in much of the rough country west of the Missouri. In the Black hills are ponderosa pine, spruce, aspen, white birch and cedar. Animals widely found include deer and antelope. Buffalo and prairie dogs can still be seen in Black hills preserves. Pheasants can also be found.

Parks, Historic Sites and Recreation.—The state has 170 state and federal parks, recreational areas, camps and picnic grounds. Included in this number are the Mt. Rushmore National memorial, Wind Cave National park, Custer State park in the Black hills area, the Badlands National monument and the Gavins Point dam and Fort Randall dam recreation areas.

NED HAINES FROM RAPHO-GUILLUMETTE

SCENE IN THE BADLANDS NATIONAL MONUMENT SHOWING EFFECTS OF EROSION

The gigantic sculptured faces of Washington, Jefferson, Lincoln and Theodore Roosevelt at Mt. Rushmore are the greatest single tourist attraction in the state, followed by the weird landscape of the Bad Lands of the White river. Camping is especially popular in the Black hills and at federal dams along the Missouri. There are extensive facilities for boating and fishing in the Black hills, in the northeastern region of the glacial lakes, at Lewis and Clark lake above Gavins Point dam and at the Fort Randall dam. The state boasts some of the best pheasant hunting in the nation and is also on the flyway of ducks and geese. Deer are hunted in the Black hills and in some eastern counties. Antelope, once the most popular game animal at frontier army posts, are hunted in western sections of the state.

Sites of great historic interest include a number connected with the periods of exploration and Indian warfare. At Ft. Pierre a small monument marks the place where Louis and François Verendrye buried a lead plate in 1743, claiming the region for the king of France. Ft. Wadsworth, near the Sisseton Indian reservation, has been restored and is maintained by the state. Points visited by Lewis and Clark include Spirit mound, near the town of Vermillion. The site of the Wounded Knee massacre of 1890 is on the Pine Ridge reservation. Yankton, the capital of Dakota Territory from 1861 to 1883 and onetime river port, has many fine old homes as well as a Territorial museum.

HISTORY

Mound Builders resided in the area that is now South Dakota prior to A.D. 1200. Evidence of their occupation has been found in 22 counties east of the Missouri. The Arikara, an agricultural and village dwelling Indian people, inhabited the region after 1600. The first white men to visit the area were the Verendrye brothers, who came into northwestern South Dakota via the Mandan villages of North Dakota in 1742 and may have visited the Black hills. On March 30, 1743, they planted a lead plate on a hilltop on the site of what was later Ft. Pierre, claiming the land for France. The plate was recovered by three school children in 1913.

In 1762 the area was ceded to Spain, and it was under Spanish rule that fur traders began visiting this part of the St. Louis trade empire. The arrival of fur traders coincided with the arrival of the Sioux or Dakota Indians, pushing westward from the woodlands of Minnesota and driving the Arikara upriver before them. Under Napoleon France reclaimed Louisiana, but held it only three years before selling it to the United States in 1803. Lewis and Clark crossed the state in the course of their explorations.

The fur trade on the upper Missouri reached its peak in the 1830s and 1840s. Ft. Pierre, started as a fur trading post in 1817, became the capital of a fur territory of 250,000 sq.mi. Among the principal traders were Manuel Lisa, Pierre Chouteau and Registre Loisel. In support of fur traders Col. Henry Leavenworth in 1823 led a small party of U.S. soldiers and a motley array of trappers, traders and Indian allies against the Arikara at the mouth of the Grand river. In 1831 the "Yellowstone," the first steamboat on the upper Missouri, traversed the state. For more than 50 years thereafter steamboats provided the readiest means of access to the Dakota frontier.

Settlement.—No attempt at settlement by persons other than traders was made until 1856, when land speculators from Iowa and Minnesota, drawn by the prospects of water power at the falls of the Big Sioux river, located there. Indian title had been surrendered by the treaty of Traverse des Sioux of 1851. These settlements were abandoned at the time of the War of the Indian Outbreak in 1862. A permanent settlement was effected at Yankton in 1859, following a treaty with the Yankton Sioux. Three years later, with the creation of Dakota Territory, Yankton became its capital. In the next decade fewer than 12,000 people migrated to the territory, establishing settlements largely along the Missouri and its lower tributaries, the Big Sioux, Vermillion and James rivers.

Rate of settlement increased with the completion of a railroad from Sioux City to Yankton in 1872 and to Sioux Falls and Watertown in 1878. The Black hills expedition of Gen. George A. Custer in 1874, which confirmed rumours that gold was to be found there, also hastened the development of the territory; this invasion of unceded lands contributed directly to the warfare in which Custer lost his life in 1876. The richest gold deposits were found in the area of Deadwood (*q.v.*) and Lead. With favouring rains, settlement reached boom proportions in the 1880s, tripling the territorial population and filling in the lands east of the Missouri, largely with north Europeans.

Statehood.—Efforts to organize as a state were hampered by Democratic opposition in congress, it being known that South Dakota as a state probably would vote Republican. The Republican party had emerged victorious in 1876 by such a narrow margin that its opponents were reluctant to add to Republican strength in congress or in the electoral college. In the election of 1888, however, Republicans captured control of both houses and the presidency, making statehood a certainty and influencing Pres. Grover Cleveland to sign the enabling act under which North and South Dakota were subsequently admitted to the union, simultaneously, on Nov. 2, 1889.

its support to higher education. Also during the post-World War II period, the Black hills became a major tourist attraction. The gigantic sculptured monument of Washington, Jefferson, Lincoln and Roosevelt, carved on the face of Mt. Rushmore by Gutzon Borglum, was opened to the public in 1942.

GOVERNMENT

The 1889 constitution provides for a bicameral legislature (35 senators and 75 representatives). It met annually from 1964, when it held its first annual session. The governor is nominated by direct primary while most other state officers are nominated by party convention. The constitution is notable for its detailed provisions, a reflection of a populistic distrust of legislatures. In addition, the constitution can be amended by a simple majority vote of legislature and electors. Amendments have been added at the rate of approximately one per year. Most notable is the 1898 amendment which provides for initiative and referendum, South Dakota having been the first state to adopt such measures. The state's 5 supreme court judges, serving for 6 years, and its 20 circuit judges, serving for 4 years, are elected on a nonpolitical ballot.

The state has no personal income tax and ordinarily levies no general property tax. Among the states, South Dakota ranks fourth to seventh from the bottom in per capita payment of state taxes. Sales and use taxes and motor fuel taxes account for more than 60% of all revenue from taxes. After World War II expenditures for highways amounted to roughly one-third of all state expenditures. The other leading items of expenditure were education and social welfare. With the retirement of rural credit bonds in 1954, the state became free of debt.

The next decade was marked by drought and a national economic depression. The distress of Dakota farmers is well described in the works of Hamlin Garland, whose parents had settled near Aberdeen. Farm discontent found expression in wide support of the Populist movement, including the election of a Populist governor and a sweep of the state for William Jennings Bryan in the "free silver" presidential campaign of 1896 (*see* POPULIST PARTY). With the return of prosperity, however, the state resumed its normal Republican course in politics, to be disturbed again only by a flurry for Theodore Roosevelt when he ran as a Progressive in 1912, and by Democrats Franklin D. Roosevelt in 1932 and 1936 and Lyndon B. Johnson in 1964. Democratic governors were elected in periods of farm protest, W. I. Bulow in 1926, re-elected in 1928, Tom Berry in 1932, re-elected in 1934 and 1936, and Ralph Herseth in 1958.

The Republican party frequently has been divided between standpatters and progressives. The latter faction was responsible for constitutional amendments that permitted the state (1915–25) to enter into a variety of business affairs, including rural credits, state bonding, state coal mining, state hail insurance, state cement plant and state guarantee of bank deposits. The state cement plant proved to be highly remunerative, but the other ventures, particularly rural credits, left the state in debt for the next 30 years.

Settlement of the lands west of the Missouri awaited the extension of rail lines and the concentration of Indians upon smaller reservations in the decade before World War I. Further development of the state also was advanced by the discovery of dry farming techniques and the development of plant types adapted to the region. Highway bridges across the Missouri were not constructed until the 1920s. South Dakota suffered greatly during the period of drought, grasshoppers and low farm prices of the 1930s. The dust storms, whipped up from areas where several years of above-normal rainfall had encouraged farmers to plow under the native buffalo grass, were worst in 1934 and 1935. Cash farm income fell to one-third of its former level. In a single year (1933) one farm out of every ten in the state was taken from its owner through foreclosure or tax sale. After World War II, on the other hand, only 1 farm in 1,000 was ordinarily foreclosed or sold for taxes in any one year. At one time nearly two-fifths of the people of the state were on government relief.

By mid-century life on South Dakota farms had improved in many ways. Tenancy and mortgage indebtedness were at a record low. In 1930 seven-eighths of all farms were located on dirt or unimproved roads. With more adequate revenues, the state legislature after 1945 appropriated large sums for interstate and farm-to-market roads. Under Gov. Joe Foss the state greatly increased

POPULATION

The area which now forms South Dakota had 11,776 inhabitants in 1870 and 348,600 in 1890. The population of the state in 1910 was 583,888; in 1940, 642,961; in 1950, 652,740; and in 1960 680,514. This last figure represented an increase of 4.3% over the population in 1950. The population per square mile in 1960 was 8.8, as compared with 8.5 in 1950 and with 49.6 for the United States in 1960.

Of the 1960 population 262,180, or 39.3%, lived in incorporated places of 2,500 or more, as compared with 33.1% in 1950 and 24.6% in 1940. The state has one standard metropolitan statistical area, which is Sioux Falls. This area had a total population of 86,575 or 12.7% of the total population of the state in 1960.

*South Dakota: Places of 5,000 or More Population (1960 census)**

Place	Population				
	1960	1950	1940	1920	1900
Total state	680,514	652,740	642,961	636,547	401,570
Aberdeen	23,073	21,051	17,015	14,537	4,087

Watertown	14,077	12,699	10,617	9,400	3,352
Yankton	9,279	7,709	6,798	5,024	4,125

*Populations are reported as constituted at date of each census.

The number of occupied dwelling units (or households) in 1960

was approximately 217,000, as compared with 190,000 in 1950 and 165,000 in 1940. The average population per household had declined from 3.9 in 1940 to 3.6 in 1950 and to 3.1 in 1960.

The population of the state was distributed by colour and nativity in 1960 as follows: 93.3% native white; 2.7% foreign-born white; and 4.0% nonwhite, almost all Indians. Most of the Indians (nearly all Sioux) live on the state's eight reservations. Of the foreign-born white population a large proportion were born in Scandinavian countries. Germany and Russia also provided significant numbers of immigrants.

In 1960 there were 102.4 males per 100 females in the total white population, and 101.9 in the total nonwhite. Of the total population, 10.5% were 65 years old or over, and 54.8% of the population 14 years old and over were in the labour force. Of the total number of employed persons, 30.5% were engaged in agriculture, 6.4% in construction, 6.6% in manufacturing and 18.9% in wholesale and retail trade.

EDUCATION

Public Schools.—Approximately nine-tenths of the state's primary and secondary school pupils attend public schools. State aid amounts to about 10% of the cost of public education. A high proportion of local property taxes goes to its support, and in many localities school authorities have found it difficult to operate within prescribed mill levy limitations. School reorganization in rural districts is not compulsory, and many common school districts do not operate schools, preferring to pay tuition at other schools for the limited number of children in their own districts. This is particularly true for high school students.

Higher Education.—The University of South Dakota, at Vermillion, is the chief state institution of higher education. Established in 1882, it is governed, along with the other state institutions, by the Regents of Education, State of South Dakota, a seven-member board appointed by the governor with the consent of the state senate. The university comprises schools and colleges of arts and sciences, business, education, fine arts, law, medicine and nursing. It enrolls about 2,500 students annually; the faculty numbers almost 300.

The state also supports the South Dakota State College of Agriculture and Mechanic Arts at Brookings (1883); the South Dakota School of Mines and Technology at Rapid City (1885); and state teachers' colleges at Aberdeen (1901), Spearfish (1883), Springfield (1881) and Madison (1881).

Private institutions of higher education include Augustana college at Sioux Falls (Lutheran, 1860), Dakota Wesleyan university at Mitchell (Methodist, 1885), Huron college at Huron (Presbyterian, 1883), Sioux Falls college (Baptist, 1883) and Yankton college at Yankton (Congregational, 1881).

HEALTH, WELFARE AND CORRECTIONS

The South Dakota department of public welfare provides old-age assistance, aid to dependent children, the disabled and the blind, and general assistance. The state maintains one prison and one training school.

THE ECONOMY

Agriculture.—South Dakota leads all the states in the proportion of personal income derived from agriculture (more than 28%). The economy of the state is thus subject to wide fluctuations, varying with both the market and the weather. Approximately two-thirds of cash farm income is derived from livestock and products; alfalfa, corn and oats are commonly sold "on the hoof" rather than as cash crops. Only in the northeastern and north-central sections do cash crops amount to as much as one-half of cash farm income. The average size of farms in the southeastern section is more than 225 ac.; in the northern wheat areas it is 800 ac.; and in the western range sections, 3,000 ac. In all sections the trend is toward larger farm units and fewer operators.

The state's leading crop is corn, nearly all hybrid strains that have helped to increase yields and to extend the corn area north and west within the state. Sorghum grain is planted as a substitute for corn during extended periods of drought, and in small amounts at other times. Production of corn averages a little over 100,000,000 bu. on approximately 4,000,000 ac. of land. The state usually ranks ninth in the production of corn.

Wheat production, both in acres harvested and in total yield, varies more widely than does corn production. During years of good rain large areas of range land have been plowed up and planted to wheat. This was particularly true during World Wars I and II, which were also periods of high wheat prices. As much as 4,000,000 ac. of land have been planted to wheat, but government quotas reduced this to between 2,000,000 and 3,000,000 ac. In spite of these limitations, total production increased. The state usually ranks tenth in the production of all wheat and second in the production of durum wheat. South Dakota is usually among the first five states in numbers of beef cattle and calves and among the first ten in numbers of hogs and sheep. Milk production is concentrated in the eastern quarter of the state, near to urban centres, while sheep are raised primarily in the northwestern counties. The state ranks tenth in wool production.

Irrigation is carried on extensively in only a few localities. The largest federal reclamation project is Oahe dam on the Missouri, designed to provide water for lands in the James river valley. The Belle Fourche project dates from 1908, the Shadehill dam from 1950 and the Angostura dam from 1952. Other irrigation is carried on along the arid fringes of the Black hills and, by means of wells, in scattered localities in the humid eastern parts of the state.

Manufacturing.—Meat packing and processing of dairy and poultry products are the leading industries, accounting for nearly two-thirds of all workers in manufacturing. Printing and publishing rank next, followed by lumber and wood products.

Mining.—South Dakota ranks first among the states in the production of gold and beryl, second in feldspar, columbium-tantalum and lithium minerals and third in lignite. Between $16,000,000 and $20,000,000 worth of gold is mined annually. The Homestake mine at Lead is the largest gold mine in the western hemisphere. Sioux quartzite and a mahogany-coloured granite are quarried in the eastern part of the state. Uranium ores were discovered in the Black hills in 1951. There are a small number of oil wells, the first dating from 1953. There are undeveloped deposits of low-grade manganese ore near Chamberlain and low-grade uraniferous lignite in the northwestern section of the state.

Transportation and Communication.—The first railroad reached the southeastern corner of South Dakota in 1872, but it was 1881 before the Chicago and North Western and Milwaukee lines reached the central part of the state; it was 1907 before the Missouri river was bridged and east-west rail connections established to the Black hills. There are nearly 4,000 mi. of rail lines in the state. Yankton, Dakota Territory, was a thriving port for steamboats prior to 1881, but the new railroad facilities of that year reduced river traffic to short hauls. The construction of a network of highways, begun in the 1920s, was interrupted by depression and war, but after World War II highway construction claimed the largest share of the state budget. The completion of five Missouri river bridges (1924–26) was a major milestone in establishing the state trunk system which, by the 1960s, consisted of more than 7,000 mi. of highway. Eleven cities are served by commercial airlines; the state has more than 30 public airports.

Current statistics on production, employment, industry, etc., may be obtained from the pertinent state departments; the principal figures are summarized annually in the *Britannica Book of the Year*. (E. W. St.)

SOUTHEAST ASIA usually denotes the area comprising the East Indies (Greater and Lesser Sunda islands, Moluccas, and Philippines) and the Indochinese peninsula of continental Asia. Mainland Southeast Asia consists principally of a series of roughly parallel, north–south-trending ranges and valleys, associated with some of Asia's larger rivers; *e.g.*, the Mekong and the Irrawaddy

(*q.v.*; the principal river in Burma). Insular Southeast Asia includes several geologically unstable island-arcs, possessing an abundance of active volcanoes, as well as a stable zone (Borneo, eastern Sumatra, and nearby areas) resting on the Asian continental platform. The climate is predominantly tropical, with annual rainfall generally above 40 in. (1,000 mm.). The natural vegetation is forest.

The area is highly diversified culturally, although Malaya and the East Indies, with strong affinities among their languages, are a partial exception. Rice and maize are the principal dietary staples. Southeast Asia is an important source of rubber, rice, coconut oil, sugar, teak, Manila hemp, tea, coffee, tobacco, and pepper, and of tin, petroleum, bauxite, and other minerals. Industry is poorly developed. Prior to the 16th century, Southeast Asia had commercial and other contacts with India and China, and in several places, *e.g.*, Cambodia, Sumatra, Java, had evolved high civilizations. From the 16th to the 20th centuries the area was influenced by the West, all portions except Thailand becoming colonies of western powers. By 1963, however, all parts of Southeast Asia had achieved independence except Portuguese Timor; Brunei was independent under British protection.

Turbulence, crises, and change marked the 1960s in much of Southeast Asia. Tensions over positions there continued between the West and Communist China and between the West and the U.S.S.R. For the war and political events in Vietnam, *see* VIETNAM: *History;* the role of the U.S. in the war is also covered in UNITED STATES: *History. (J. M. BT.; X.)

SOUTHEAST ASIAN LANGUAGES. Southeast Asia is one of the great linguistic treasure houses of the world, both in number of languages and in the complexity of their interrelationships. Burma alone is reported to have between 125 and 140 languages spoken within its borders. Although national languages like Vietnamese, Cambodian, Thai, Malay, and Burmese are literary languages with a centuries-old tradition, others, like the Karen languages and Shan, have acquired a writing system only within the past hundred years. Until the mid-20th century little was known about most of the remaining languages. Since World War II, however, both Western and Japanese scholars have concerned themselves increasingly with many hitherto neglected nonliterary languages.

Linguistic diversity of this degree is the result of the fact that Southeast Asia has been, for untold millennia, a crossroads between India and China and between these and the great islands of the Pacific. At the same time long contact among diverse families has given rise to certain broad similarities characteristic of a linguistic area. Prominent cross-genetic features include the widespread use of status and kin-term pronominals, of numeral classifiers, and of complex verbal strings (*e.g.*, take-come-give, meaning "bring it to me"). As a consequence, even quite unrelated languages like Thai and Cambodian offer greater ease of intertranslatability than either does with English.

Three important linguistic families are represented: (1) Austronesian or Malayo-Polynesian; (2) Mon-Khmer; and (3) Sino-Tibetan. Actual linguistic reconstructions based on well-attested phonetic correspondences have been worked out only for the Austronesian family. Malay (Malaya) is the principal representative of this family on the Southeast Asian mainland. Mon-Khmer, in its narrowest sense, includes Mon (Burma) and Cambodian, or Khmer (Cambodia). Sino-Tibetan may be conservatively described as having three branches: (1) Tibeto-Burman; (2) Chinese; and (3) Tai. Tibeto-Burman, named after the two great literary languages, Tibetan (Tibet) and Burmese (Burma), also includes many nonliterary languages, *e.g.*, Lushai, Garo, and Bodo (Assam), Jingphaw or Kachin (Burma), and possibly the languages of the Chins and Nagas (Burma) and the Lolo (southwestern China). The Karen languages (Burma and Thailand) may also be related. The best-known Tai languages are Thai, or Siamese (Thailand), Lao (Laos), and Shan (Burma). Many lesser-known languages also unquestionably belong here, including the extinct Ahom (Assam), and Dioi, Tho, Nung, Lung-chow, and Wu-ming (northern Vietnam and southern China), as well as others.

The above description of family affiliations leaves many questions unanswered. One theory places Chinese and Tai together in a single subfamily on a par with Tibeto-Burman in Sino-Tibetan. According to another theory, however, Tai is not related to Chinese at all (or to Tibeto-Burman) but is affiliated with Austronesian. Much the same kind of confusion is found with other Southeast Asian languages. Vietnamese is classified now as a Mon-Khmer language, now as a Tai affiliate, but has never been proved related to any other language. The much-debated Austroasiatic hypothesis attempts to encompass the Munda languages (India), Khasi (Assam), Nicobarese (Nicobar Islands), Semang, and Sakai (Malaya and southern Thailand), as well as Mon-Khmer, Vietnamese, and Muong. Miao and Yao (China) are sometimes added, but other students favor a Tai or Tibeto-Burman affiliation.

The Austroasiatic hypothesis, tenuous as it is, has appealed to many as the starting point for other connections; *e.g.*, Austroasiatic plus Austronesian (the "Austric" theory), Austroasiatic plus Japanese, and Austric plus Sino-Tibetan. On a different axis, transpacific relationships with American Indian languages have also been suggested. Possibly deserving of further investigation is Edward Sapir's proposal, in 1925, that Sino-Tibetan (including Tai) may be related to Nadene (the Athapascan languages plus Tlingit and Haida).

Only by continuing to intensify linguistic work in Southeast Asia can we hope to reach a stage at which the interrelationships of these languages can be cogently described. Urgent needs include the linguistic reconstruction of such families as Tibeto-Burman and Mon-Khmer according to the same rigorous methods used to arrive at Proto-Austronesian and Proto-Indo-European. Progress has been made on Proto-Karen and Proto-Bodo, subbranches of Tibeto-Burman. Details regarding the consonants, consonant clusters, and tone classes of Proto-Tai are also fairly well known.

(M. R. H.)

SOUTHEAST ASIA TREATY ORGANIZATION, usually known as SEATO, is the regional defense organization created by the Southeast Asia Collective Defense Treaty signed at Manila, Sept. 8, 1954, by the representatives of Australia, France, New Zealand, Pakistan, the Philippines, Thailand, the United Kingdom, and the United States. The treaty entered into force Feb. 19, 1955.

The formation of SEATO was a response to the demand that the area be protected against Communist expansionism, especially as manifested through military aggression in Korea and Indochina and through subversion backed by organized armed forces in Malaya and the Philippines. The Republic of Vietnam and the kingdoms of Cambodia and Laos (the successor states of Indochina) were not considered for membership in SEATO for reasons largely relating to the 1954 Geneva agreements ending the fighting in Vietnam. These states were, however, accorded military protection by a protocol. Other nations of south and Southeast Asia preferred to retain their foreign policies of nonalignment.

The treaty area is the general area of Southeast Asia, including the entire territories of the Asian members and the general area of the Southwest Pacific south of latitude 21° 30′ N. The treaty defines its purposes as defensive only and includes provision for self-help and mutual aid in preventing and countering subversive

activities directed from without, and cooperation in promoting economic progress and social well-being.

SEATO has no standing forces but is based upon the mobile striking forces of its member states, which regularly engage in combined military exercises. A secretary-general, acting under the direction of the council or its representatives, heads an international staff in Bangkok which supplements the work of the organization's expert committees on public relations, area security, cultural affairs, and certain economic matters. (R. W. Z.)

SOUTHEND-ON-SEA, a county and parliamentary borough and seaside town of Essex, Eng., 39 mi. (63 km.) E of London Bridge by road, on the Thames estuary facing south. Pop. (1961) 165,093. Area 16.1 sq.mi. (42 sq.km.). The borough includes Leigh-on-Sea, Westcliff-on-Sea, Thorpe Bay and Shoeburyness. With its 7-mi. seafront it is one of England's largest seaside towns and the nearest to London. It has gardens, beaches, an open-air theatre, yachting, a carnival week, magnificent illuminations from August to late October, and a pier (1⅓ mi.) which accommodates pleasure steamers. The oldest part of the borough is Prittlewell where the priory (1110) has housed the museum since 1917. Southchurch Hall (13th century) is a public library and Porters (Tudor) is the civic house. Southend became fashionable as a seaside resort when visited by Princess Charlotte of Wales in 1801 and her mother Princess Caroline in 1803.

It was incorporated in 1892, became a county borough in 1914, and a parliamentary borough in 1918. It returns two members. Besides providing for more than 5,000,000 annual holiday makers, Southend's many industries, mostly on the new industrial estate, include radios and televisions, electrical apparatus, glass blowing, and engineering.

SOUTHERN ALPS, New Zealand: *see* New Zealand: *Physical Geography.*

SOUTHERN AND ANTARCTIC LANDS, FRENCH (Terres Australes et Antarctiques Françaises). These barren lands, which were linked for administrative purposes with Madagascar (now the Malagasy Republic) from 1924, were not effectively occupied till 1949 (mainly by scientific personnel). In August 1955 they became a territory of the French Union, later French Community, governed under special statute by a senior administrator who is partially resident in Paris. The lands comprise: (1) in the south Indian Ocean, and in a temperate cold climate, the Islands of Saint Paul and Nouvelle Amsterdam; (2) in a subantarctic climate, the Kerguelen and Crozet groups of islands; and (3) Adélie Land on the Antarctic continent.

Nouvelle Amsterdam and Saint Paul.—These are two volcanic islands (Nouvelle Amsterdam, area 19 sq.mi. [50 sq.km.] in latitude 37° 52′ S, longitude 77° 32′ E; Saint Paul, area 2.7 sq.mi. [7 sq.km.] in 38° 43′ S, 77° 31′ E). Nouvelle Amsterdam is an extinct volcano (2,953 ft. [900 m.]); the crater of Saint Paul has been filled by the sea. The temperature varies from 5° to 20° C (41° to 68° F) with an average of 12° (53.6°). Fog is frequent and the westerly winds are strong. Mosses, bracken, grasses, and a scattering of trees (*Phylica arborea*) grow there. Animal life consists mainly of seabirds, fish, and crayfish. Access to the islands is difficult.

Magellan's companions discovered Nouvelle Amsterdam in 1522. Fishermen from Réunion used to visit the islands, and France annexed them in 1843. In 1949 a permanent radio-meteorological station, Camp Heurtin, was established at Nouvelle Amsterdam. Research stations, an administrative office, and a hospital were also established there.

Kerguelen.—Kerguelen, lying in latitude 49°–50° S and longitude 69°–70° E, covers about 2,700 sq.mi. (7,000 sq.km.). It is volcanic and has a certain similarity to Iceland. It comprises one main island and about 300 small islets. The main island is broken into ravines by glacial erosion, and has many peninsulas and fjords, chiefly in the east. The Cook Glacier occupies the west; Mont Ross in the south reaches 6,430 ft. (1,960 m.). Temperatures are not excessively low, averaging 0° C (32° F) in the winter and 6° (42.8°) in the summer. Rain and snow are frequent, the west wind is strong, and the sea is often rough. The vegetation consists solely of two flowering bushes (*Acaena* and *Azorella*), some enormous seaweeds, and the edible "Kerguelen's Land cabbage" (*Pringlea antiscorbutica*). There are numerous seabirds, including penguins, petrels, cormorants, sheathbills, skuas, and albatrosses. The chief of the several species of seal that go to Kerguelen to breed is the huge elephant seal (*Mirounga leonina*). The rabbit, introduced by man, has become a pest.

Kerguelen was discovered in 1772 by the French navigator Yves Joseph de Kerguelen-Trémarec who took possession of it. The island was explored in 1776 by Capt. James Cook, who called it the Island of Desolation, and since then it has been frequented by seal hunters. In 1950 a permanent base and scientific centre, Port-aux-Français, was established on the east coast. It has a hospital, military camp, and seal-oil plant. Reindeer, sheep, poultry, and vegetables have been introduced. There are lignite beds and peat bogs, and some semiprecious stones have also been found. About 100 persons (relieved at regular intervals) live on the island, which is served by chartered vessels and also has an airstrip.

Crozet Islands.—Discovered by Capt. Marion Dufresne and his mate, Crozet, in 1722, these comprise two groups of volcanic islands between latitude 45°–47° S and longitude 50°–52° E: (1) the Islands of Cochons, Pingouins, and Apôtres, together with several small islands; (2) Île de la Possession, which rises to 6,560 ft. (2,000 m.), and Île de l'Est, which is glacier covered. The total area is 193 sq.mi. (500 sq.km.). The coasts are steep. Climate, vegetation, and animal life are similar to those of Kerguelen. The islands, uninhabited, have been made a national park.

Adélie Land.—Adélie Land (Terre Adélie), discovered by J.S.C. Dumont d'Urville in 1840, is situated south of Australia on the edge of Antarctica between longitude 136° and 142° E. It is a plateau of ancient rocks covered by ice and has an area of about 150,600 sq.mi. (390,000 sq.km.). It can be reached only in summer, during which the average temperature is 0° C (32° F). In winter the temperature averages −30° C (−22° F), and blizzards reach 125 mph. Whales, seals, petrels, and penguins were the sole inhabitants until 1950 when A. F. Liotard set up the first station at Port Martin. D'Urville Base was established at Pointe Géologie in 1952. Exploratory teams have penetrated more than 300 mi. into the interior.

See also Antarctica.

See Edgar Aubert de la Rue, *Les Terres australes* (1953); *Terres australes et antarctiques françaises* (quarterly). (Hu. De.)

SOUTHERN DESERT TERRITORY (Al Badiyah al Janubiyah), a region in the extreme southwest of Iraq, bordering Saudi Arabia. The region was in 1947 formed into one of three *liwa*'s or provinces (along with the Northern Desert Territory and Al Jazirah) from what had previously been termed tribal areas and left undemarcated. Area 29,399 sq. mi. (76,143 sq.km.). The population is of mixed tribal allegiance, mainly Anaiza ('Unayzah) and Amarat ('Imarat), with many Dhafir and Muntafiq and some others. The region lies astride a main pilgrimage route southwest from Karbala but otherwise has few international connections and trade links. The population is almost entirely nomadic, and there are no important settled centres. By 1960 the territory had ceased to be a *liwa'*, and its area and population had been administratively attached to the settled *liwa*'s. (W. B. Fr.)

SOUTHERNE, THOMAS (1660–1746), Irish-born dramatist, was long famous for two sentimental tragedies successfully acted until well into the 19th century—*The Fatal Marriage, or The Innocent Adultery* (first produced in 1694 and known after Garrick's adaptation in 1757 as *Isabella, or The Fatal Marriage*), and *Oroonoko* (1695). Both were based on novels by Aphra Behn (*q.v.*); both owed much to Thomas Otway in their mingling of pathos with a sometimes flaccid rhetoric. *The Fatal Marriage* anticipated 18th-century domestic tragedy, while *Oroonoko* showed affiliations with the earlier heroic plays of Dryden. Isabella, first acted by Mrs. Barry, gave Mrs. Siddons one of her major successes a century later. The character of Oroonoko, an African prince enslaved in the English colony of Surinam, marks one of the first literary appearances of the "noble savage."

Southerne was born at Oxmantown, Dublin, and entered Trinity College, Dublin, in 1676. Probably in 1680 he went to London and in July of that year was admitted to the Middle Temple, where

he presumably remained until 1682, when his first play, *The Loyal Brother, or The Persian Prince*, was produced at Drury Lane. In 1685 he received a commission in Princess Anne's Regiment of Foot, but his military career ended with the Revolution of 1688. As well as writing seven other plays—lively comedies of manners and frigid tragedies in Roman settings—he made some contribution to Dryden's tragedy *Cleomenes* (1692), and was well known for recommending plays to the theatre, including Congreve's *The Old Bachelor* (1693) and Colley Cibber's *Love's Last Shift* (1696). He died in London on May 26, 1746.

BIBLIOGRAPHY.—*Plays . . .* , 3 vol. (1774); modern editions of *Oroonoko* in *Five Restoration Tragedies*, ed. by B. Dobrée (1928); and of *The Loyal Brother*, ed. by P. Hamelius (1911). *See* also J. W. Dodds, *Thomas Southerne, Dramatist* (1933). (C. LE.)

SOUTHERN OVERLAND MAIL, the service established in the United States in 1858 for carrying mail and passengers by stagecoach from St. Louis to San Francisco. Earlier U.S. mail service to the Pacific coast had been slow and unreliable. Beginning in 1849, the year of the gold rush, mail was carried by steamboat to the Isthmus of Panama, over the isthmus by mule or canoe, and then up to California by steamboat. Inadequate overland mail service was provided along a central route through Salt Lake City, Utah, in 1851. Thereafter, demands mounted for greater government support for overland service. The problem was complicated by the bitter quarrels of the period between Southerners and Northerners in Congress. In March 1857 Congress passed an overland mail bill that left the choice of route to the postmaster general, Aaron V. Brown of Tennessee. He chose a southern route, defending it as the best all-weather route. In September 1857 John Butterfield of Utica, N.Y., and several associates signed a contract with the U.S. government to transport letter mail over the southern route from St. Louis, Mo., and Memphis, Tenn., by way of Fort Smith, Ark., El Paso, Tex., Tucson and Yuma, Ariz., and Los Angeles to San Francisco, Calif., and back "twice a week in good four-horse post-coaches or spring wagons, suitable for the conveyance of passengers as well as the safety and security of the mails." Butterfield and his associates were to receive a government subsidy of $600,000 a year for six years, 1858–64. The first eastbound mail on the new route left San Francisco on Sept. 15, 1858, and the first westbound mail left St. Louis on the following day.

Although northern critics objected to the circuitous route—2,795 mi. from St. Louis to San Francisco—the service proved satisfactory. The contractors were able to provide the 25-day service they promised. Stations were built at intervals of 15 mi. or less, and the coaches carried passengers as well as mail. Unfortunately for the contractors the American Civil War interrupted service and made it necessary to move the line to a central route on July 1, 1861. The contract was transferred to Ben Holladay in 1862, and he in turn transferred his interests to Wells, Fargo and Company in 1866. The completion of a transcontinental railroad in 1869 brought cancellation of the last contract for carrying overland mail by stagecoach. *See* also PONY EXPRESS.

SOUTHERN PROVINCE, CEYLON, covers an area of 2,146 sq.mi. (5,558 sq.km.) of southernmost Ceylon and had a population (1953) of 1,129,308. It consists for the most part of coastal lowland crossed by rivers, the more important of which are the Nilwala Ganga and Walawe Ganga. In the western part of the province the relief is more prominent and more confused; it includes the southern part of the Rakwana Hill mass, which rises to more than 4,000 ft. Apart from coastal sands and alluvium, Southern Province is made up entirely of ancient crystalline rocks.

The western part of the province (Galle and Matara districts and Giruwa Pattu west of Hambantota District) lies in the wet zone of Ceylon and has a rainfall of 70 in. (1,800 mm.) or more, well distributed throughout the year; the hillier areas of the interior are particularly wet. The rest of the province is in the dry zone and is subject to a searing seasonal drought from May to September. The extreme east is particularly dry. Natural vegetation has largely disappeared from the wet zone, though some forests and fernlands remain; much of the dry zone is still under tropophilous forest, which passes into poor scrub as the driest areas are approached. In this region is Ruhunu (Yala) National Park (50 sq.mi. [130 sq.km.]), where elephant, bear, leopard, deer, and other wild animals may be studied. (*See* also CEYLON: *Physical Geography.*)

Ruhunu is the traditional name for an area wider than the present Southern Province, and it functioned as one of the two main core areas of ancient Sinhalese civilization. The part of Southern Province lying in the dry zone, together with the belt transitional to the wet zone, was of great importance, as is witnessed by the many surviving ruins, irrigation works, and inscriptions. The ruins of the ancient city of Magama are at Tissamaharama. Wet zone places, such as Matara, later became more prominent. It was the area in the wet zone that was particularly valuable to the Portuguese and Dutch, who used Galle and Matara, in particular, as fortified trading posts.

Low-country Sinhalese form the majority of the population. The wet zone is densely peopled, but apart from occasional areas of denser settlement the dry zone has a sparse population, the extreme east being virtually empty. The main towns are Galle (*q.v.*), capital of the province (55,848), Matara (*q.v.*; 27,641), and Hambantota (4,299), all district capitals; others are Weligama (12,834), Ambalangoda (10,554), and Tangalla (6,823).

The province has a varied economy. The wet zone produces rice, coconut, rubber, tea, cinnamon, and citronella. In the dry zone rice growing under new or restored irrigation works is of increasing importance. Fishing is also carried on. A coastal railway runs from Colombo to Galle and Matara, the latter being the railhead. The road network is adequate in the wet zone and rather rudimentary in the dry zone. (B. H. F.)

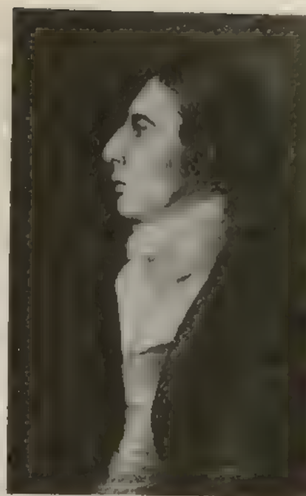
SOUTHEY, CAROLINE ANNE (née BOWLES) (1786–1854), English writer, the second wife of Robert Southey (*q.v.*), whose correspondence with her reveals both at their best. The daughter of an East India Company captain, she was born at Buckland Cottage, near Lymington, Hampshire, on Oct. 7, 1786. After her mother's death (1816), a guardian's fraudulence left her almost penniless, and, knowing of Southey's kindness to poor poets, in May 1818 she sent him a metrical tale, *Ellen Fitzarthur* (anon. 1820). Thus began a correspondence lasting until their marriage, on June 4, 1839. Southey encouraged her writing and at their first meeting (London, 1820) suggested subjects and treatment; she, on her side, showed unfailing sympathy and understanding of his work, criticizing it with lively wit and fancy. She stayed at Greta Hall (1823), and Southey visited her at Buckland. During his wife's illness, and after her death (1837), her friendship comforted him, but he lived only four years after their marriage. After his death she returned to her old home: her step-daughter Kate Southey's jealousy had provoked a family quarrel. She died at Buckland on July 20, 1854.

Of her writings, most notable are the poems in *The Widow's Tale* (1822) and *The Birthday* (1836); the verse *Tales of the Factories* (1833); the prose stories in *Chapters on Churchyards* (2 vol., 1829); and *Robin Hood*, on which Southey collaborated, published as a fragment (1847). Southey's comment, in his first letter, "You have the eye, the ear and the heart of a poetess," had truth; but her talent was slender, and her charming personality is only fully seen in her letters.

See J. F. Burnet in the *Fortnightly Review*, CLXXIII (1953); and bibliography to SOUTHEY, ROBERT.

SOUTHEY, ROBERT (1774–1843), English writer who is remembered chiefly for his association with Wordsworth and Coleridge (*qq.v.*) as one of the Lake poets, though his poetry has little in common with theirs and is now esteemed less highly than his prose. The son of a linendraper, he was born in Bristol on Aug. 12, 1774, but spent much of his childhood at Bath in the care of Elizabeth Tyler, his mother's eccentric half sister. In 1788 he entered Westminster School, London, but was expelled in 1792 for an attack on corporal punishment in *The Flagellant*, a school magazine that he and his friends had founded. This in-

justice roused his rebellious nature, and, already enthusiastic for the ideas of the French Revolution, when he entered Balliol College, Oxford, in December 1792, soon after his father's bankruptcy and death, he expressed ardent sympathy for it in a long poem, *Joan of Arc* (published 1796).



BY COURTESY OF THE NATIONAL PORTRAIT GALLERY, LONDON

ROBERT SOUTHEY, PENCIL AND WATER-COLOUR PORTRAIT BY R. HANCOCK, 1796

In June 1794, Coleridge, on a visit to Oxford, met Southey and outlined his plans for a "pantisocracy," or utopian agricultural community, on the banks of the Susquehanna in the United States. They met again at Bristol in August, and Southey (who had left Oxford without taking a degree) introduced Coleridge to Sara Fricker, whom he was later to marry. Robert Lovell, another friend (who collaborated with Southey in a volume of poems, published in the autumn, 1794; titlepage, 1795), had already married Mary Fricker, and Southey himself soon became engaged to a third sister, Edith. Miss Tyler objected both to the engagement and to "pantisocracy"; she barred Southey from her house and never saw him again. To raise funds for their plan, Southey and Coleridge turned to lecturing in Bristol and to journalism: they had already produced a verse drama, *The Fall of Robespierre*, published in 1794 as by Coleridge. The dream of "pantisocracy" faded, and, soon after secretly marrying Edith Fricker at Bristol (Nov. 14, 1795), Southey left for Portugal with his uncle, Herbert Hill, who was chaplain to the British colony at Lisbon. He had already decided, against his uncle's wishes, not to take holy orders. While in Portugal he wrote the letters published as *Letters Written During a Short Residence in Spain and Portugal* (1797) and learned to thank God that he was an Englishman, thus beginning the change in his political opinions that turned him from revolutionary to Tory. On his return (May 1796) he made public his marriage and in February 1797 began to study law in London. In 1797 he also began to receive an annuity of £160, paid for nine years by a Westminster schoolfriend, Charles Watkyn Williams Wynn, who later became a cabinet minister. In 1797–99 he published a second collection of poems, in two volumes, including some from the 1794 volume.

The Southeys soon left London, and Southey gradually abandoned the law. They lived partly at Westbury-on-Trym, near Bristol, where (1798–99) he wrote many of his best short poems and ballads, among them "The Ebb-Tide," "Bishop Hatto," and "The Battle of Blenheim"; and partly at Burton, Hampshire. During this time Southey was contributing regularly to the *Morning Post* and other newspapers and reviews, translating, working on the epic *Madoc* (published, fully revised, 1805), and editing Chatterton's works (published 1803). On a second visit to Portugal (1800–01), made partly to recover from serious illness, he gathered material for a history of that country and completed his epic poem *Thalaba the Destroyer* (1801). Life abroad deepened his conservatism, finally confirmed by the Peace of Amiens (1802) and replacement of Pitt (whom he hated) by Addington.

Having returned to England (May 1801), in August the Southeys visited Greta Hall, Keswick, where Coleridge (to whom Southey, after an estrangement, was now reconciled) was living. This, his first visit to the Lake District, made little impression, and after a fortnight he set off for a tour in north Wales. Early in September he accepted the post of secretary to Isaac Corry, the Irish chancellor of the exchequer. Still undecided about his future, he gave up the job in May 1802, and, depressed by the deaths of his mother and (August 1803) of his first child, a daughter (b. 1802), on Sept. 7, 1803, he and his wife joined the Coleridges and Mrs. Lovell (whose husband had died in 1801) at Greta Hall. They were to remain there for the rest of their lives.

Deciding temporarily to abandon poetry, which he found too exciting to his nature, he took up his *History of Portugal*, of which only the *History of Brazil* (3 vol., 1810–19) was published. The birth of five daughters (1804–12), of a second son, Herbert (1806), and the dependence on him of the household, especially after Coleridge left his family, forced him to apply himself conscientiously and unremittingly to authorship—producing poetry, history, biography, criticism, and journalism of various kinds. In 1807 he published, anonymously, the *Letters from England: By Don Manuel Alvarez Espriella*, a fictitious Spaniard; and, in the same year, an edition of the works of Henry Kirke White (2 vol.; vol. III, 1822), a young protégé who had died in 1806. In 1809 he became a regular contributor to the new Tory *Quarterly Review*, for which he wrote, anonymously, a series of 95 political articles for the next 29 years: at first concerned mainly with foreign policy, these later expounded his plans for social reform, authoritarian but farseeing in demanding state provision of "social services." In 1813, through the influence of Sir Walter Scott, he was appointed poet laureate, and in 1835 the government pension of £160, secured for him by Wynn in 1807, was increased to £300. His fame as a poet and critic grew steadily. An interval of domestic happiness was interrupted by the death of the brilliant, much-loved Herbert (1816), although the birth of Charles Cuthbert (1819) somewhat restored his naturally buoyant spirits.

In 1817, an unauthorized publication of an early verse drama, *Wat Tyler*, was used by the Radicals to remind the public of his youthful republicanism. His change of principle had irritated Byron (*q.v.*), who had already attacked Southey in *English Bards and Scotch Reviewers* (1809), and who, in 1818, dedicated *Don Juan* to the laureate in a set of ironic stanzas. Byron believed, mistakenly, that Southey had spread scandal about himself and Shelley, so that when, in the introduction to *A Vision of Judgement* (1821), Southey continued the quarrel by denouncing Byron as belonging to a "Satanic school" of poetry, he replied in the brilliant satire of *The Vision of Judgement* (1822).

Southey's later years were saddened by his wife's illness: she became insane in September 1834 and died on Nov. 16, 1837. In 1839 he married Caroline Bowles (*see* SOUTHEY, CAROLINE ANNE), but his mental and physical powers were already failing. He died at Greta Hall on March 21, 1843, and was buried at Crosthwaite, Keswick. Family quarrels about his second marriage resulted in the erection of three memorials: the monument in Crosthwaite Church bears an inscription by Wordsworth, referring to his "wide aims" and "life to heaven vowed."

Critical Assessment.—Southey's poetry is little read today, though the two longer poems, *Thalaba* and *The Curse of Kehama* (1810), both in irregular verse, the former unrhymed, the latter rhymed, are good and readable examples of the Oriental verse tale. Of his minor poems, such lyrics as "My Days Among the Dead Are Passed" are still read, and his comic-grotesque ballads, *e.g.*, "The Inchcape Rock," are unexcelled in English except by *The Ingoldsby Legends*. His poetic theory is expounded in the prefaces to the collected edition of 1837–38. He regarded poetry as the noblest of all vocations and constructed his poems on high moral, even heroic, principles; but they lack the creative genius of Wordsworth and Coleridge.

His more ambitious prose works are not entirely satisfactory. *The Life of Wesley; and the Rise and Progress of Methodism* (1820), a standard, though controversial, work in its day, and his valuable edition of Cowper (15 vol., 1835–37) have been superseded, as have most of his historical works. Only *The Life of Nelson* (2 vol., 1813; often reprinted) remains a classic. It is in his less formal work that his gifts are most happily displayed: in *Sir Thomas More: or, Colloquies on the Progress and Prospects of Society* (1829); in the anonymously published *The Doctor* (7 vol., 1834–47), a fantastic, rambling novel miscellany, packed with anecdotes (including the famous "Story of the Three Bears"), comments on life and literature, and quotations from his wide reading; and in *Espriella's Letters*, which gives a lively picture of English life. In these, and in his correspondence, Southey's prose is masterly, modeled on that of Defoe and Swift, with an ease and

clarity found in no other writer of his time. Byron called his style "perfect," Hazlitt said that it could "scarcely be too much praised," and it has been particularly admired by such modern critics as Sir Herbert Read and Jack Simmons.

(1856); *Correspondence . . . with Catherine Bowles, etc.,* ed. by E. Dowden (1881); *Letters . . . A Selection,* ed. by M. H. Fitzgerald, "World's Classics" (1912).

Biography and Criticism: J. Simmons, *Southey* (1945), the best modern biography, includes a short bibliography of Southey's works. *See* also E. Dowden, *Southey,* "English Men of Letters Series" (1874); W. Haller, *The Early Life of Robert Southey, 1774–1803* (1917). There are reminiscences by contemporaries, references in Wordsworth's correspondence and in that of Byron and Coleridge (*see* bibliographies to the articles on them), and criticism in Coleridge's *Biographia Literaria,* Hazlitt's *Spirit of the Age,* and Landor's *Imaginary Conversations.* For Southey's political opinions, *see* G. D. Carnall, *Robert Southey and His Age* (1960). (N. C. N.)

SOUTH GATE, an industrial and residential city of central Los Angeles County, Calif., U.S., is 12 mi. (19 km.) S of the Los Angeles civic centre and a part of the Los Angeles metropolitan area (*see* LOS ANGELES). Prior to 1915 the area of South Gate was devoted to truck farming. Heavy industry was encouraged to come in, and South Gate's growth has been continuous since. It was incorporated as a city Jan. 20, 1923, and in 1958 established a council-manager form of government. Manufactured products include automobiles, fibreboard products, auto tires, chemical products, and airplane parts. Pop. (1960) 53,831. For comparative population figures *see* table in CALIFORNIA: *Population.* (J. M. Wo.)

SOUTH GEORGIA: *see* FALKLAND ISLANDS AND BRITISH ANTARCTIC TERRITORY.

SOUTH HOLLAND (ZUIDHOLLAND), the most densely populated province of the Netherlands, borders the North Sea and adjoins the provinces of North Holland to the north, Utrecht and Gelderland to the east, and North Brabant and Zeeland to the south. Area 1,234 sq.mi. (3,196 sq.km.). Pop. (1960) 2,706,810. The province consists of a coastal strip of dunes and sandy soil (*geestgronden*), a low-lying inland region of peat and fluviatile clay, and, in the south, an archipelago (in rapid transition under the Delta plan; *see* NETHERLANDS, THE: *Dikes and Polders*) formed by the ramifications of the Lek, Waal, and Maas (Meuse) rivers, the largest islands being Dordrecht, Voorne-Putten, Hoeksche Waard, and Goeree-Overflakkee, all with soils of marine clay. On the inner side of the dunes, which was early populated, are the old towns of Leiden, The Hague, and Delft (*qq.v.*). The Hague is the capital of the province and the seat of the Netherlands government.

Whereas the dunes are mainly used for recreational and residential purposes (Scheveningen, Katwijk aan Zee, and Noordwijk aan Zee are important seaside resorts), the geest is mostly devoted to horticulture. Northward from Leiden, bulbs are grown exclusively, and at Keukenhof, near Lisse, there is a famous annual exhibition of flowering bulbs. Northwest of Leiden, in the Rijnsburg area, vegetables and flowers are grown. South of The Hague, as far as the New Waterway, is the Westland, a district of intensive horticulture where fruit and vegetables (especially tomatoes, cucumbers, and grapes) are grown under glass.

By far the most important part of South Holland is the port and industrial district of Rotterdam (*q.v.*), which extends along the New Waterway and the Lek, Noord, and Merwede rivers, and of which The Hague, Delft, Gouda, Dordrecht, and Gorinchem are the outposts. Industries include shipbuilding, engineering, oil refining (Pernis and Europoort), and chemical manufacture (Vlaardingen, Rozenburg, and Botlek).

The inland clay and peat region is given to agriculture in the reclaimed lakes and to cattle farming on the older soils, cheese making being of particular importance in the eastern districts. Pot plants and shrubs are grown at Boskoop. A number of interesting old towns, *e.g.,* Vianen, Schoonhoven, Oudewater, and Woerden, are situated on the rivers; Gouda (*q.v.*) is the service centre for this region.

Arable farming predominates in the archipelago; local specialities include onions (Overflakkee). An old town in this region, Brielle, an ancient port (the capture of which by the *Watergeuzen* [*see* GUEUX] in 1572 was the signal for the revolt against the Spaniards), has become a recreation centre for Rotterdam since the closing of the Brielse Maas in 1950. *See* also HOLLAND, COUNTY AND PROVINCE OF. (H. J. KE.)

SOUTH INDIA, CHURCH OF, came into existence in September 1947, as the result of the merger, after 28 years of negotiation, of the Anglican, Methodist, Presbyterian, and Congregationalist groups with the Basel Mission (Lutheran and Reformed), in the area of India south of the Vindhya Mountains. The union was based on the acceptance of the Holy Scriptures as the supreme authority in faith and life, of the so-called Nicene Creed as the authorized summary of the faith, of the sacraments of baptism and Holy Communion, and of the historic episcopate in constitutional form. Provision was made for a 30-year period of growing together, in the course of which it was hoped that the union would become complete. On the day of the inauguration, nine new bishops, drawn from all the contributing traditions, were consecrated to serve with the five Anglican bishops already in office, in the 14 (later 16) dioceses of the united church. None of the ministers in office were reordained, and all were regarded as equally eligible for election to any office in the church.

No attempt was made to impose uniformity at once on all the local churches, which were to continue to use their accustomed liturgical forms until genuinely Indian forms of worship could be worked out by agreement. The church later issued orders for Holy Communion, baptism, ordination, and other services; these are not mandatory, but use of them expanded steadily. The order for Holy Communion has been highly praised by liturgists but has nothing of specially Indian character. Yet the church is unmistakably Indian, independent of control from other church bodies outside India.

The church has a membership of more than 1,000,000 baptized adherents; their number has grown steadily, though slowly, and without any notable new mass movement toward Christianity. The church has full communion with the nonepiscopal bodies from which in part it sprang, but not with all Anglican churches, though Anglican clergy or laity serving in the Church of South India do not enter into schism.

The Church of South India marked a new beginning, as it was the first instance since the Reformation of union between episcopal and nonepiscopal churches. As such it aroused passionate controversy, which still continues. In its intention to extend the union, it engaged in conversations with the Baptists and Lutherans of the area. Conversations with the Baptists lapsed, but agreement was reached with the Lutherans on doctrinal points, though not on all questions of organization.

See also CANON LAW: *Church of South India.*

BIBLIOGRAPHY.—B. G. M. Sundkler, *The Church of South India* (1954); A. M. Ward, *The Pilgrim Church* (1953); R. D. Paul, *The First Decade* (1958); *Book of Common Worship of the Church of India* (1963). (S. C. N.)

SOUTH MOLTON, a municipal borough of Devon, Eng., lies 12 mi. (19 km.) SE of Barnstaple by road, on the River Mole. Pop. (1961) 2,993. The parish church of St. Mary Magdalene is mainly Perpendicular, and the market square has many Georgian houses. In 1357 the town was granted a charter to hold a market and annual fair, which still take place, and there is also a large annual sheep fair. Incorporated in 1590, the town was granted another charter in 1684. South Molton is an ideal tourist centre for Exmoor and the Doone Valley. Its industries (besides textile factories) are mainly agricultural. (L. J. WE.)

SOUTHPORT, a municipal (1867), county (1905), and parliamentary borough, Lancashire, Eng., is a popular seaside resort. It also has a large residential population, being 20 mi. (32 km.) N of Liverpool and 39 mi. NW of Manchester and connected by rail to both cities. Pop. (1961) 82,004. The town developed in the 19th century on the coastal sand dunes, the ground inland being

marshy. There are extensive beaches, pleasure gardens, a long pier, and several parks and handsome thoroughfares, notably Lord Street. An important annual flower show is held. Southport is a golfing centre, the courses including Royal Birkdale. Light engineering is the most important industry.

SOUTH PORTLAND, a city of Cumberland County in southwestern Maine, U.S., separated from Portland (*q.v.*) by Portland Harbour and tidal Fore River. South Portland was originally part of Cape Elizabeth, which divided over the offer of the Portland Water District to supply the town with Sebago Lake water; some of the Cape Elizabeth people were opposed, but residents of the salt-water-lapped southern section, who were unable to dig enough freshwater wells, welcomed the offer. The region was set off and incorporated as the town of South Portland on March 15, 1895, and was granted a city charter a week later. A city-manager system was instituted Jan. 1, 1934. During World War II, Liberty ships were built in South Portland; the shipyards were later taken over by three steel-fabrication firms and by a Canadian company for an oil pipeline terminal. The city also became the site of one of the largest Atlantic coast oil-tank farms. For comparative population figures *see* table in MAINE: *Population*. (A. K. GL.)

SOUTH SAN FRANCISCO, an industrial city of California, U.S., 9 mi. (14 km.) S of San Francisco (*q.v.*) and just north of San Francisco International Airport, on San Francisco Bay. The city is built upon Spanish land bought in 1869 for the "cattle empire" of Henry Miller and Charles Lux; in the 1890s financiers and industrialists led by G. F. Swift of the meat-packing firm planned a workers' community there. The tract was subsequently subdivided and incorporated in 1908. The location offered excellent rail and water transportation and inexpensive factory sites, and industrialization continued. By the city's 50th anniversary important industries included steel, paint and chemicals, and meat-packing. Housing expanded rapidly during and following World War II. For comparative population figures *see* table in CALIFORNIA: *Population*. (J. H. ST.)

SOUTHSEA: *see* PORTSMOUTH.

SOUTH SEA BUBBLE, the name given to a speculation mania that ruined many English investors in 1720, closely following the French financial crisis of the previous year. This so-called bubble (or hoax) centred on the fortunes of the South Sea Company founded by Robert Harley in 1711 to trade with Spanish America, on the assumption that the War of the Spanish Succession would end with a treaty under which such a trade (mainly in slaves) might be opened. The company was given a monopoly of trade to South America and the Pacific. Holders of navy and ordnance bonds were offered stock, with a guaranteed interest of 6%, and the stock was accepted willingly. But the peace treaty, when made, conveyed only a very limited trading concession, restricted to a single annual ship that could not enter the Pacific. The success of the first voyage in 1717 was only moderate, but in the following year the king became governor of the company, creating fresh confidence in an enterprise that soon yielded up to 100%. There had been a first wave of speculation when the Bank of England was founded in 1694, but the postwar boom of 1713–19, paralleled by the Mississippi Company mania in France, now gave rise to extravagant hopes. Those who were unable to buy South Sea stock (which was genuine, if overcapitalized) were consoled by optimistic investors and swindlers with the offer of shares in a hundred dubious ventures.

South Sea stock itself stood at 128½ in January 1720, rose to 330 in March, 550 in May, 890 in June, and stood at 1,000 in July and August. In September it dropped to 175 and in December to 124. Other shares followed a similar trend, Bank of England stock falling from 263 to 145.

The occasion of the boom in South Sea shares was the scheme by which in 1720 the company took over the whole of the national debt except that owed to the Bank of England and the East India Company and persuaded the investors to exchange their state annuities for South Sea stock, sold at a tremendous premium. Though a few investors profited greatly, far more were ruined. Some fled from their creditors and not a few committed suicide.

This financial disaster was followed by an inquiry undertaken by a committee of the House of Commons. Its report, rendered in February 1721, showed that at least three ministers had both accepted bribes and speculated in the stock. John Aislabie (1670–1742), chancellor of the exchequer, was expelled from the House and imprisoned. The Earl of Sunderland and Charles Stanhope were acquitted by small majorities, and the estates of the company's directors were mostly confiscated. The company itself continued to exist, making fair profit until 1732, selling most of its rights to the Spanish government in 1750 but retaining some privileges until 1807 and its existence until 1853. In its later years it was concerned mainly with the Greenland whale fishery and for a short time numbered Charles Lamb among its clerks.

The scandal surrounding this company in 1720 weakened the whole system of chartered companies (*see* CHARTERED COMPANY) and provided arguments for free trade. Another result of the affair was the destruction, indirectly, of the London slave trade, to the immediate profit of Bristol and to the eventual profit (on a far greater scale) of Liverpool.

SOUTH SHIELDS, seaport, municipal, parliamentary, and county borough, Durham, Eng. Pop. (1961) 109,521. Area 7.6 sq.mi. (20 sq.km.). It is on the south side of the mouth of the River Tyne, there protected by the massive South Pier, nearly 1 mi. long. Ferries connect the town with North Shields. Shipbuilding and repairing and marine engineering are important, and there is considerable export of coal and iron. The Tyne dock has a water area of 50 ac., and the tidal basin is 5¾ ac. Roman Remains Park, near the northern end of the town, may have been an island in the Tyne; the remains comprise storehouses, etc. The town was founded by the convent of Durham in the 13th century. In the 17th and 18th centuries it had large glassworks and salt pans. The first self-righting lifeboat was launched there in 1790. The town has returned one member to Parliament since 1832, and in 1850 it was incorporated, being raised to county borough status in 1889.

SOUTHWARK, one of the 32 boroughs constituting Greater London, Eng., established in 1965 under the London Government Act 1963 (*see* LONDON) and formed by the amalgamation of three former metropolitan boroughs, Bermondsey, Camberwell, and Southwark. Area 11.5 sq.mi. (30 sq.km.). Pop. (1961) 312,761. The borough stretches from Sydenham Hill to the south bank of the Thames, which is crossed by Blackfriars, Southwark, London, and Tower bridges, and Cannon Street Railway Bridge. It consists of three parliamentary constituencies.

Historically, Southwark's northern area has always been important as a meeting place of roads from the south and as the commanding point to the approach to London Bridge. There was a Roman settlement there, and the main roads (Old Kent Road, Borough High Street, Newington Causeway, and Newington Butts) follow Roman routes. After the building of the other Thames bridges that connect Southwark with the City, the Elephant and Castle area became a major traffic junction. Southwark's river frontage is lined with wharves and warehouses. The Surrey Commercial Docks (381½ ac. [154 ha.]) are at Rotherhithe. Because of its position Southwark has long been a busy commercial area. The docks and warehouses handle much of London's food. The London Provision Exchange is at No. 1 London Bridge, and several famous firms are engaged in food processing and brewing. The Borough Market (fruit and vegetables) dates from the 18th century. A traditional Bermondsey industry is leather, and the National Leathersellers' College is in Southwark. There are also various printing and engineering firms. Dulwich and parts of Camberwell are largely residential.

The borough is served by Southern Region and Underground railways. The Metropolitan Line which links Rotherhithe with Wapping (in Tower Hamlets) uses a tunnel constructed (1825–43) beneath the Thames by Sir Marc Isambard Brunel.

After the Reformation the medieval Augustinian priory of St. Overie became the parish church of St. Saviour; in 1905 it became

the cathedral for the Southwark diocese. The church was rebuilt in the 13th and 15th centuries and the nave restored in the 19th. The tower is 15–16th century. The Harvard Memorial Chapel commemorates John Harvard, the founder of Harvard University, who emigrated to New England from Southwark in 1637. St. George's Roman Catholic Cathedral, designed by A. W. N. Pugin in 1848, was largely rebuilt after severe damage sustained during World War II air raids. The Camberwell parish church of St. Giles, designed by Sir George Gilbert Scott, occupies the site of an earlier church that was destroyed by fire in 1841. The Bermondsey parish church of St. Mary Magdalene was rebuilt in 1680. St. Mary's Church at Rotherhithe, a riverside landmark, has many memorials to seamen, including Christopher Jones, captain of the "Mayflower." The Pilgrim Fathers' Memorial Church has been rebuilt in Great Dover Street. The Metropolitan Tabernacle at the Elephant and Castle, built 1861 for Charles Haddon Spurgeon, the Nonconformist preacher, has been reconstructed but retains its impressive facade.

Guy's Hospital was opened in 1725. The chapter house of Southwark Cathedral was formerly the chapel of St. Thomas' Hospital, founded 1213 and removed to Lambeth in 1868. Maudsley Hospital is on Denmark Hill.

Educational institutions include Dulwich College (founded 1619, rebuilt 1870), Wilson's Grammar School (1615), St. Olave's and St. Saviour's Grammar School (originally two separate 16th-century foundations), the Camberwell School of Arts and Crafts (1898), the London College of Printing (at the Elephant and Castle), and the William Booth Memorial Training College (1929) on Denmark Hill. The South London Art Gallery and Cuming Museum are both administered by the borough. The Cuming Museum deals mainly with local history. The Dulwich College Picture Gallery was the bequest mainly of Sir Francis Bourgeois (*see* DULWICH). The Imperial War Museum occupies buildings originally erected in the early 19th century to house the Bethlehem Royal Hospital (*see* BEDLAM). Open spaces include Peckham Rye Common and Park (103 ac. [42 ha.]), Dulwich Park (75 ac.), and Southwark Park (66 ac.).

Chaucer's Canterbury pilgrims started from the Tabard Inn in Borough High Street. Many of Shakespeare's plays were first produced at the Globe Theatre on Bankside, the site also of the Rose (noted for plays by Marlowe), the Swan, and the Hope theatres. An annual Shakespeare Festival is held in the borough. Many scenes in Dickens' novels are set in Southwark, and St. George's in Borough High Street is familiarly known as the Little Dorrit Church. Robert Browning was born in Camberwell, John Ruskin lived at Herne Hill and Denmark Hill, and Michael Faraday was born at Newington Butts.

Bermondsey, Camberwell, Southwark, Rotherhithe, Peckham, and Walworth all appear in Domesday Book. Old Southwark, traditionally known as "The Borough," was from 1295 to 1547 the only town besides the City in the present Greater London area to be represented in Parliament. In 1327 Edward III granted Southwark to the citizens of London, and it became known as "The Bridge Ward Without." Several great ecclesiastics had houses on Bankside, notably the bishop of Winchester. The many famous inns in Borough High Street have been rebuilt except for the south wing of the George (rebuilt 1676), the last surviving galleried inn in London (now owned by National Trust). The medieval history of Bermondsey was dominated by its great Cluniac abbey, founded in 1082; Bermondsey Square approximately marks its site. Until the 19th century much of Southwark was rural, with farms and market gardens. A spa and various country inns were places of resort for Londoners. The Thames bridges, the railways, and the general increase in population led to rapid urbanization, often accompanied by poverty and overcrowding. The architecture where not post-World War II is predominantly Victorian; wartime destruction and large-scale redevelopment schemes completely changed parts of the old borough, notably the Elephant and Castle area. (M. J. Bo.)

SOUTHWELL, ROBERT (1561–1595), English poet and martyr, remembered for his saintly life as a Jesuit priest and missionary in England during a time of persecution, his heroic endurance of torture and death, and his religious poetry, which anticipates that of George Herbert and Richard Crashaw (*qq.v.*). Born at Horsham St. Faith, near Norwich, in 1561, he was brought up as a Catholic and in 1576 was sent to the Jesuit English College at Douai. From there he went to Clermont, the Jesuit college in Paris, and in 1577 he was sent to Rome, where in October 1578 he became a novice. In 1585 he was ordained priest and made prefect of studies at the English College at Rome.

He had determined, however, to return to England as a missionary and in 1586 persuaded his superiors to allow him to accompany Henry Garnett (*q.v.*) to London. They arrived in July, and, after spending some time in hiding at the house of Lord Vaux at Hackney, Southwell became chaplain to Anne Howard and spiritual adviser to her husband, the first earl of Arundel, who, as a recusant, was imprisoned in the Tower. He lived in concealment at Arundel House in the Strand, London, writing letters of consolation to the earl and other persecuted Catholics and making pastoral journeys to Catholic families outside London. One of his letters, *An Epistle of Comfort . . .* , was printed on an illicit press in 1587; others circulated in manuscript.

After many narrow escapes, Southwell was arrested when celebrating mass in a Catholic household at Uxendon, near Harrow, Middlesex, on July 5 (new style; June 26, old style), 1592. He was taken first to the house of Richard Topcliffe, the head of the pursuivants, as those employed in seeking out Catholics were called, where he was tortured in an attempt to make him reveal the whereabouts of his fellow priests. He was then transferred to the Gatehouse, a prison in Westminster, and, after his father had petitioned the queen that he might be put to death rather than stay in such a "filthy hole," to the Tower. There he was kept for three years in solitary confinement. At last, in 1595, he was brought to trial on a charge of treason under the anti-Catholic penal laws of 1585, and on March 4 (N.S.; Feb. 22, O.S.) he was executed at Tyburn.

Southwell's theme is always religion, and his devotional lyrics and prose treatises and epistles—mainly written at Arundel House and published only after his death—reflect the ardent piety of his life. His best works achieve an unusual directness and simplicity, and in his use of paradox and parallelism and of striking imagery he is akin to the 17th-century metaphysical poets. He has a secure place as the foremost representative of Catholic letters in Elizabethan England.

BIBLIOGRAPHY.—Southwell's poems were edited, with introduction, by A. B. Grosart (1872). Selections in L. I. Guiney (ed.), *Recusant Poets* (1938); shorter poems ed. by C. M. Hood, as *The Book of Robert Southwell* (1926); *An Humble Supplication* (1600, dated 1595; ed. by R. C. Bald, 1953). *See* also P. Janelle, *Robert Southwell the Writer* (1935), the first authoritative biographical study; C. Devlin, *The Life of Robert Southwell* (1956).

SOUTHWELL, a town and rural district of Nottinghamshire, Eng., 14 mi. (22 km.) NE of Nottingham by road. The rural district of 55 parishes had a population (1961) of 45,850; area 185.2 sq.mi. (480 sq.km.). It has hosiery works, a flour mill, and an interest in the neighbouring market-garden area (Bramley seedling apples are said to come from Southwell), but is chiefly known for its minster, a successor of a 7th-century church generally attributed to Paulinus; certainly there was a church there in the 8th century.

The present building was begun in the 12th century and has a Norman nave, transepts and towers, an Early English choir and a Decorated octagonal chapter house. It is cruciform and is 306 ft. long. There are no cloisters. Particularly noteworthy are the magnificent 14th-century stone rood screen, intricately carved, and the carved animals and foliage on the doors of (and within) the chapter house.

In 958 land at Southwell was granted to the archbishop of York by Edwy and a detailed description of the manor appears in Domesday Book. Southwell was a collegiate establishment and remained under the lordship of the see of York until it was taken over by the ecclesiastical commissioners. Remains of the archbishop's palace (15th-century; "great chamber" restored 1880) are incorporated in the bishop's palace.

The episcopal see founded in 1884 included the counties of Not-

tingham and Derby, but the latter was detached in 1926 when the see of Derby was established.

SOUTHWEST, THE. This term has been in use in the United States for more than 150 years to denote a geographic area, and its meaning has changed over the years as the nation has expanded. After the War of 1812, the Southwest generally meant Missouri, Arkansas, and Louisiana. After Texas was annexed, it too, was included. In the wake of the war with Mexico, the Southwest embraced most, but not all, of the territory acquired under the Treaty of Guadalupe Hidalgo (1848; *see* MEXICAN WAR). California's littoral and great interior valleys were so different in physiography and development that the term never settled easily upon them. Rather, the Southwest came to mean, by and large, the 900-mi. stretch of arid land between the 100th meridian and the deserts athwart the lower Colorado River; *i.e.*, New Mexico, Arizona, and such contiguous parts of Texas, Oklahoma, Colorado, Utah, and Nevada as suited the convenience of the person using the term.

Early explorers found a diverse and difficult topography. The high, dry plains of Texas, sliced in the north by such unexpected abysses as Palo Duro Canyon, rose imperceptibly to the Pecos Valley of New Mexico, a dividing line that the myriads of buffalo farther east seldom crossed. Beyond the Pecos and embracing its headwaters were the southern spurs of the Rocky Mountains, cool with evergreens. West of the Rockies came vast horizontal strata of highly coloured sandstone; in places these beds formed broad peneplains whose dry monotony was broken by occasional mesas or buttes. Where the beds were higher they were cut by spectacular gorges, three of which—Zion and Bryce canyons in Utah and the Grand Canyon of the Colorado River in Arizona—became national parks. Still westward, beyond a forested uplift that cut across Arizona from northwest to southeast, lay the true deserts marked by prickly plant growths and parallel chains of north-south mountains, gaunt and almost devoid of vegetation.

The common denominator of the land was aridity. Although the highest peaks of New Mexico and Arizona caught 30 in. (750 mm.) of rain or more a year, the annual average was less than half that amount; indeed, the western deserts might receive only 2 in. (50 mm.) or less. Except for the snow on the mountains, the bulk of this scanty precipitation came during violent thunderstorms; the flash floods they produced did much to give the region its scarred and angular topography.

High temperatures and rapid evaporation intensified the dryness. Precipitation that would support dry farming in the Dakotas or Nebraska proved, generally speaking, inadequate in the Southwest: crops could be grown there only with irrigation. Yet the region's two principal rivers, the Colorado and the Rio Grande (both of which rose outside the area), as well as the smaller streams of the local mountains could be tapped at only a handful of widely scattered spots. This overwhelming geographic fact turned some of the prehistoric Indians into sedentary agriculturalists (for these aboriginal peoples, *see* INDIAN, NORTH AMERICAN: *Culture Provinces*), determined the shape of the Spanish occupation, and ultimately led the American inhabitants to an alliterative folk description of their economy as one of "copper, cattle, cotton, and climate."

Despite oversimplification, there is much to justify this summation. Geologic evidence even suggested that aridity might have had some bearing on the Southwest's huge deposits of low-grade copper ore, the so-called porphyry coppers. Mexicans were working the richer streaks of the long-productive ore body at Santa Rita, N.M., before 1800; other veins were opened in southeastern Arizona following the Civil War. However, the great development came after 1910 when the handling of enormous tonnages by power shovels in open-pit mines lifted Arizona to first place among the copper-producing states. Compared with this outpouring of copper, the Southwest's brief stampedes for gold and silver and later for oil and uranium achieved little more than regional significance.

The dryness of the land enforced a pastoral agricultural economy that began in 1598 when Juan de Oñate established in the Rio Grande Valley of New Mexico the first permanent colonies of the western United States. (San Antonio, Tex., and San Xavier del Bac near Tucson, Ariz., were not founded for another century; San Diego, Calif., not until 1769). Because of the difficulty of supervision cattle were not popular with the first settlers. Horses, however, multiplied rapidly and were soon spread among the Indians by barter and theft. Sheep ranches grew to enormous size—in the early 1800s New Mexico's governor, Bartolomé Baca, owned 2,000,000 head—and social cleavage was largely between those who owned sheep and those who herded them. The Pueblo Indians (*q.v.*) took readily to the animals and learned to weave wool just as they were already weaving a native cotton. The Navaho learned the craft from the Pueblo, developed their famous blankets, and as late as World War II accounted for half the sheep raised in Arizona (*see* NAVAHO).

During the period of Spanish ascendancy, the sheep were driven to market among the silver mines of Mexico. In the 1850s the California goldfields offered an outlet for those owners willing to brave the long trek across mountains and desert to the coast. After the Civil War the demand of the new Southwestern Indian reservations and army posts for beef lured herds of longhorns west from Texas. When the Apaches of the mountains were brought under control, permanent establishments took root in New Mexico and Arizona, sometimes in violent conflict with rival sheep ranches. High profits made overgrazing of the public domain a more serious threat to the economy of the Southwest than the Indians ever were. Only federal control, exerted through an increasing number of agencies, was able to check the trend and start restoring the ranges.

Other federal intervention came in the management of water resources. Irrigation had been practised before A.D. 1000 by the Pueblo Indians in New Mexico and central Arizona. The Spanish added a few *acequias* or "ditches" of their own, often as part of the huge land grants belatedly made by the Mexican government in the hope of establishing agricultural communities as buffers against the encroaching Americans. In their turn these Americans, individually and through cooperatives, struggled to increase the paltry stream diversions; but measures commensurate with the problems were not possible until the Reclamation Act of 1902 made available the resources of the national government.

The Reclamation Service's first successful large-scale project in the nation was Theodore Roosevelt Dam near Phoenix completed in 1911. The largest project in the Southwest was Hoover Dam on the Colorado River, completed in 1936 (though the Glen Canyon Dam, upriver from Hoover, completed in 1964, closely approached it in size). But the water proved expensive and led to intensive cultivation of high-income crops: alfalfa, citrus, and long-staple cotton. It also led, in the case of streams crossing state boundaries, to complex legal disputes, the bitterest of which concerned the diversion of the Colorado River water far from its natural channels. Various state compacts were entered into by the claimants, but sectional jealousies militated against a satisfactory solution. After World War II the water shortage was made even more critical when developments associated with aviation and nuclear energy brought an unprecedented influx of industry and population into all of the Southwest's urban areas.

Though the crisp climate and scenic landscapes were a curse to agriculture, they were a boon to businesses catering to tourists and health-seekers. These visitors, it was shortly discovered, had a lively interest in the once-despised cultures of the Indians and Spanish-Americans. The heavily beamed, flat-roofed Indian pueblo, as modified by the Spanish, became the inspiration for the region's new architecture. Indian dances, Spanish fiestas, and cowtown rodeos, catching hold first as tourist attractions, became the year's social and economic high points for scores of communities. Although the showier forms of this evolving culture were not truly typical of any of its founding strains, they fixed themselves, in the popular mind at least, as an even more distinctive feature of the American Southwest than the ancient angular topography and dazzling sunlight.

For bibliography, *see* the articles on the several states and on the main rivers, COLORADO RIVER and RIO GRANDE. (D. S. L.)

SOUTH WEST AFRICA (SUIDWES-AFRIKA), a territory of southern Africa that came into being as a German protectorate in 1890 and developed under German control until it was invaded by forces from the Union of South Africa in 1915. After the

Treaty of Versailles the territory was mandated to the Union. It is still administered as a mandated territory of the Republic of South Africa. Extending from the Orange River in the south to the Kunene and Okovango (Okavango) rivers and the parallel of 17° 23′ S in the north, the territory extends to the Chobe and Zambezi rivers in the Caprivi Zipfel (Caprivi Strip) between northern Botswana (Bechuanaland) and southeastern Angola. Its eastern boundary south of this strip lies on the meridian of 21° E as far south as the 22nd parallel and then on the meridian of 20° E to the Orange River. The area of the territory is 317,887 sq.mi. (823,328 sq.km.), not including the Walvis Bay enclave of 374 sq.mi. (969 sq.km.), which is an integral part of Cape Province in the Republic of South Africa, although administered as a part of South West Africa. The capital is Windhoek (*q.v.*).

Physical Geography.—*Geology and Structure.*—The territory includes four of the major geological formations of southern Africa. The Basement Complex, of old granite and gneiss, with metamorphosed sediments, forms much of the plateau surface between Windhoek and Outjo, extending from this main area northwestward into the Kaokoveld Mountains and southward along the plateau edge to the Orange River Valley. The Precambrian Damara System, of dolomite, limestone, sandstone, and metamorphosed rocks, occupies most of the plateau surface from the Khomas Highland in the Windhoek area to the Kunene on the northern border. Much of this system is strongly folded, the axes trending generally north by east. In the south of the territory the Nama System, of quartzite, shale, and black limestone, dips gently eastward. The Karroo System, comprising almost horizontal beds of tillite sandstone, shale, and overlying lava, forms the surface in the area extending from the Orange River in the south to near Gobabis in the middle of the territory. In the north it forms local plateaus such as the Waterberg and great areas of lava in the Kaokoveld. Young granites have been intruded into these beds, forming such prominent features as the Brandberg, in the Namib, and the Erongo Mountains.

The youngest formations are in the east and west. In the east the Tertiary Kalahari System, of consolidated gravels and sands at the base and a varying thickness of overlying loose sand, covers about half the territory to the north of 22° S and a considerable area to the west of the southeastern boundary. In the west of the territory the sands and clays of the Namib, together with the diamond-bearing shingle of the southern coastal strip, are probably the youngest formations.

Physiography.—Two major divisions can be recognized: the plateau surface, and the marginal zone between the plateau and the coast. Separating these divisions is the plateau edge or Great Escarpment, the highest parts of which are known in the south as the Huib (highest point 5,860 ft. [1,786 m.]), the Tsaris (6,486 ft. [1,977 m.]), and the Naukluft-Hakos (6,200 ft. [1,973 m.]) escarpments and, in the north, as the Joubertsberge (5,856 ft. [1,785 m.]) and the Baynes Mountains (7,200 ft. [2,195 m.]).

On the plateau the highest area is the Khomas Highland, whose ridges trend east-northeast through the Windhoek area. The main watershed of the territory is formed in this highland by the Auas Mountains (Moltkeblick 8,153 ft. [2,485 m.]). In the north the Otaviberge (Nageib 7,001 ft. [2,134 m.]) trend east-west in the Grootfontein area, bending northward in the Joubertsberge. In the south of the plateau area the main orographic features are the Klein and Gross Karas Mountains (Schroffenstein Berg 7,224 ft. [2,202 m.]) and Mount Brukkaros (5,203 ft. [1,588 m.]), an ancient volcanic crater, about 9 mi. (14 km.) N of Berseba, which rises 1,500 ft. (457 m.) above the Namaqualand Plain.

Most of the marginal zone is known as the Namib, generally flat and true desert near the coast, passing, as it ascends to the plateau edge, into a semidesert zone generally known as the Inner Namib. (*See* South Africa, Republic of: *Geographical Regions.*) The highest point in the territory is the Brandberg in the Namib, a young granite mass that rises precipitously to an altitude of 8,458 ft. (2,578 m.).

Five geographical regions can be recognized. (1) The Etosha Plain in Ovamboland, to the north of the Otaviberge, extending eastward to the south of the Okovango River. (2) Damaraland (or Hereroland) between the Otaviberge and the Auas Mountains, to the south of Windhoek. This is a plain of fairly even surface, which, however, is broken by many island-mountains, the highest being the Great Omatako (7,510 ft. [2,289 m.]). (3) Namaqualand (or Namaland), lying between the Auas Mountains and the Orange River, rather flat in the north but deeply dissected in the south by the Fish River and other smaller tributaries of the Orange. (4) The Kalahari surface along the eastern border, which there forms the western part of the southern Kalahari sandveld. (5) The Namib between the plateau edge and the coast, predominantly sandy in the south but behind the coastal belt becoming rocky in the north where it forms the western part of the Kaokoveld.

Drainage.—Except for the Orange in the south and the Kunene and Okovango at the northern boundary, all the rivers are of intermittent flow, "coming down" generally during two or three months of the year after the seasonal rains. The most spectacular scenery in the territory is the canyon of the Fish River, the southward-flowing tributary of the Orange. Cut in Nama beds and Archean rocks, the canyon is between 1,500 and 2,000 ft. (460 and 600 m.) deep and lies between about 27° and 27° 75′ S. In the east the Auob River has artesian conditions in its upper course. Pans (shallow temporary ponds or lakes) occur in many areas, especially on the Kalahari sand. The largest is the Etosha Pan, about 70 by 30 mi. (115 by 50 km.), which receives the summer drainage of Ovamboland.

Climate.—Because of the northward sweep of the cold Benguela Current, from the south Atlantic, along the coast, temperatures are consistently low in the Namib. Walvis Bay has a mean temperature for the coolest month (August) of 14° C (57° F) and for the warmest month (February) of 19° C (67° F). On the plateau the temperature range is greater. Windhoek, at 5,700 ft. (1,740 m.), has a mean for the coldest month (July) of 13° C (55° F) and for the warmest month (January) of 23° C (74° F). Rainfall is least in the western Namib and in the lower Orange River Valley, where the annual precipitation is less than 2 in. (51 mm.). On the plateau there is an increase of rainfall from southwest to northeast. Warmbad, in southern Namaqualand, has a mean annual rainfall of 3.4 in. (86 mm.), Windhoek 15.1 in. (384 mm.), Tsumeb 20.7 in. (526 mm.), and Katima Mulilo in the Caprivi Strip 26 6 in. (676 mm.). Except in the extreme southwest the rainfall of the territory occurs mainly in the summer months, the percentage of summer precipitation increasing steadily from southwest to northeast.

Vegetation.—In the Namib coastal zone the only vegetal types are those adapted to extreme drought. Among these are the indigenous tumboa (*Welwitschia bainesii*), the tortoise bush (*Zygophyllum stapfii*), and the edible naras (*Acanthosicyos horrida*), which grows between the dunes near Walvis Bay. Behind the coastal zone various succulents occur that give place near the plateau edge to desert grasses and aloes. In the southern part of the plateau the vegetation is predominantly of the Karroo type, with desert shrubs and succulents passing northward into grass steppe. In Damaraland and on the eastern sandveld of the Kalahari, thorn savanna (*Acacia*) with grass is the predominant type, merging to the north of the Etosha Pan into dry forest in which the mopane (*Colophospermum mopane*) is associated with large fig trees (*Ficus hereroensis*), *Hyphaene* palms, and baobabs. In the *oshanas*, or shallow floodwater channels, of Ovamboland the floors are covered with *Aristida* grasses.

Animal Life.—Primates are represented by the gray vervet monkey, the chacma baboon, and, in the north, by the bush baby (*Galago senegalensis*). Carnivores include the lion in the northwest and the northeast. The leopard and the cheetah are widespread, but the most numerous of all the larger carnivores is the brown hyena, which roams even the coastal belt of the Namib, where it lives on marine refuse and shellfish. Jackals (black-backed and side-striped) are widespread. The elephant roams the Kaokoveld, the Caprivi, and, occasionally, the Okovango area. The black rhinoceros (*Diceros bicornis*) is found in small numbers in the Kaokoveld. The giraffe and the hippopotamus also are found only in the north. Of the antelopes some, such as the koodoo (kudu), gemsbok, and springbok, are found over most of

the territory; others are limited to the northern areas, including the sassaby (tsessebe), lechwe, puku, impala, roan antelope, and the sitatunga, or marshbuck (*Tragelaphus spekei*). The hartebeest is found in the northeast and the buffalo (*Syncerus caffer*) only in the northern areas. On many of the islands off the coast to the south of Walvis Bay, and at Cape Cross farther north, the Cape sea lion or fur seal (*Arctocephalus pusillus*) is abundant.

The People.—*Anthropology.*—The nonwhite people of the territory may be divided into two main types, the Southwestern Bantu and the Khoisan types (the Hottentots and Bushmen). The Bastaards of Rehoboth Gebiet are the descendants of mixed European and Hottentot unions. The strongest Bantu groups in pre-European times were the Ambo of the north and the Herero, called Damara by the Hottentots. Occupying Hereroland (or Damaraland) to the north of the Khomas Highland, the Herero were in constant conflict with the Hottentots who occupied areas to the south of the Khomas. In the early period of German occupation the Herero, with their northern offshoot the Ovashimba, numbered probably about 100,000; they were seriously reduced under German occupation and now number about 35,000. A more primitive Bantu group, the Bergdama, or Berg (Mountain) Damaras, formerly vassals of the Herero and Hottentots, had no territory of their own but have been allocated reserves. They number about 44,000 and are probably the one native group that openly rejoices at the European occupation of the territory. They speak the language of the Nama Hottentots, who subjugated them. Hottentots, in reserves mainly in the southern part of the territory, number about 35,000. The total Bushman population in the territory is estimated at 12,000. Under German rule the area within the police zone allocated as native reserves was about 4,030 sq.mi. (10,440 sq.km.). Under the administration of South Africa the reserves were enlarged to about 79,700 sq.mi. (206,420 sq.km.), in addition to Rehoboth Gebiet, 5,060 sq.mi. (13,105 sq.km.), containing about 11,000 Bastaards, who speak Afrikaans. (*See* also AFRICA: *Ethnography* (*Anthropology*); *Southern Africa;* AMBO; BERGDAMA; BUSHMAN; HERERO; HOTTENTOT.)

Population.—At the census of 1921 the total population was 227,988, made up of 19,372 whites and 208,616 Africans and Coloured. In 1960 the total population of 526,004 comprised 73,464 whites and 452,540 Bastaards, Coloureds, and Bantu. In 1960 Windhoek had a population of 36,051, including about 19,000 whites. Populations of most of the other towns had increased considerably since 1951. The Bantu population may be divided into two groups, those in the police zone and those in the northern native territories of Ovamboland and Okovango, with small groups in the Kaokoveld and the Caprivi Strip. These territories are generally referred to as "outside the police zone." In Ovamboland (Amboland) the Ambo number about 231,000; in the Okovango territory the tribal Bantu number about 28,000. Within the police zone the native reserves in 1960 had about 26,000 Bantu, Hottentots, and Coloureds. (J. H. WN.)

History.—The first European to set foot in the territory was the Portuguese navigator Diogo Cam, who erected a pillar at Cape Cross in his voyage of 1485–86. At the end of 1487 his compatriot Bartolomeu Dias de Novais touched the coast at Walvis Bay and at Dias Point, where he erected a cross near Angra Pequena (Lüderitz). The Dutch East India Company's ship "Grundel" sailed up the coast in 1670 and was followed by the same company's "Bode" in 1677. Though the interior still remained unknown, the coastal waters were not neglected; sealing and whaling attracted ships of various nationalities. In 1793 Capt. F. R. Duminy, of the Dutch ship "Meermin," proclaimed certain areas to be the property of the Dutch government. In 1795 Capt. Thomas Alexander of H.M.S. "Star" hoisted the British flag at various points on the coast, but his action was later disowned by his government. Meanwhile, in 1760, Jacobus Coetzee found a way into Great Namaqualand by the overland route from the Cape. He was followed in 1761–62 by Henry Hop and thereafter by a fairly steady stream of explorers, of whom the most famous was C. J. Andersson, a Swede, who in 1853 crossed from Walvis Bay to Lake Ngami in Bechuanaland. The London Missionary Society was represented on the Orange River as early as 1802 and in 1807 established a station at Warmbad. This society withdrew and was succeeded by the Methodists. In the 1840s the German connection with the territory began with the arrival of the Rhenish Missionary Society.

In 1868 tribal wars prompted the missionaries to appeal for British protection. In this they were actually supported by the German government, but the British government turned the proposal down. In 1876 the Cape Colony sent a special commissioner, W. C. Palgrave, who made treaties with chiefs anxious to secure British protection. This placed the whole territory as far as the Portuguese colony of Angola under British control. The British high commissioner in South Africa approved Palgrave's action, but the British government was unwilling to assume these new responsibilities and was only with difficulty persuaded to consent to the annexation of Walvis Bay and some adjacent territory (1878). The guano islands off the coast had been annexed in 1867. In 1880 tribal war again broke out, and the German government itself asked Great Britain to protect the life and property of its subjects; the British reply was negative.

German Possession.—In 1883 Heinrich Vogelsang, agent of F. A. E. Lüderitz, a merchant of Bremen, obtained from the Hottentot chief Joseph Frederick of Bethany a cession of land at Angra Pequena, later known as Lüderitz. Bismarck, still unconverted to a colonial policy, informed the British government beforehand of the project in words that were almost an invitation to Great Britain to assume sovereignty over the territory and to act as a protecting power. This opportunity, like the previous one, was allowed to slip away, and in April 1884 Bismarck took the initiative and assured Lüderitz and his establishments of German protection, which later developed into full-fledged German annexation of the whole territory.

The first German representative, sent to the territory in 1885, was H. E. Göring. He was succeeded by Kurt von François, who transferred the capital from Otjimbingue to Windhoek. It was there that the first German farmers settled in 1892. In 1893 there was trouble with the Hottentot chief Hendrik Witbooi. The Germans attacked Witbooi's village, and 150 of his subjects, including women and children, were killed. François was succeeded in 1896 by Theodor Leutwein, who tried to treat the Africans with consideration. However, the latter found much cause for dissatisfaction, and it required only a spark to set the country ablaze. The Bondelswaartz Hottentots rose in 1903. This rising was suppressed, but early in 1904 the Herero revolted and killed a number of German (but not British or Boer) settlers. The rebellion was speedily quelled, but in the "cleaning up" operations the Herero were ferociously harried by Gen. Lothar von Trotha, Leutwein's successor from 1904, and in the end were reduced from a tribe of 80,000 people to 15,000 starving refugees. Various groups of Hottentots who had joined in the rebellion still held out until early in 1907. In the years that followed these troubles the depopulation resulting from the methods used in suppressing the rebellion caused a labour shortage that hampered the development of the territory. The discovery of diamonds in 1908 near Lüderitz Bay led to a considerable increase in the European population, which rose to nearly 15,000 by 1913.

On Aug. 6, 1914, after the outbreak of World War I, the government of the Union of South Africa undertook to assume all obligations resting upon the British regular garrison in South Africa, and on Aug. 10 to send a military expedition of its own to German South West Africa. The surrender of the Germans was forced on July 9, 1915. At the end of the campaign the German troops were interned and later (in 1919) repatriated with about 600 undesirables. German civilians, on the other hand, were allowed to return to their homes in the territory and to continue their ordinary pursuits.

The South African Mandate.—Under the Treaty of Versailles, Germany ceded its colonies to the principal Allied and associated powers. South West Africa was designated as a C mandate and was conferred on "his Britannic majesty for and on behalf of the government of the Union of South Africa." The newly created League of Nations was charged, *inter alia,* with the supervision of mandates. Subject to the mandate, South Africa was given full

powers of legislation and administration over the territory as an integral part of the Union. The exercise of these powers was vested by the House of Assembly in the governor-general (Union act no. 49 of 1919), who later delegated them to a resident administrator. The S.W.A. Naturalization of Aliens Act of 1924 provided for the automatic naturalization of all German adult males domiciled in the territory on Jan. 1, 1924, unless they specifically objected.

During the first few years of the mandate the territory was administered after the fashion of a crown colony, with an administrator assisted by an advisory council. In 1926 a Legislative Assembly of 12 elected and 6 nominated members, with an executive committee, was set up to legislate for such needs as roads and bridges, agriculture, and taxation, while the rest of the administrative functions remained in the hands of the administrator.

Until the rise of Hitler the Germans in the territory had been reasonably cooperative, but by 1939 the grip of the Nazi Party on all Germans in the territory was practically complete. At the outbreak of World War II the Union government acted with dispatch. By December 1939 about 150 Nazi leaders were arrested and the organizations themselves proscribed. By October 1940 the number of persons interned was 1,200, or one-third of the German adult male population. Under the Naturalization and Status of Aliens Amendment Act of 1942 most of the automatically naturalized Germans reverted to their former German status.

Trusteeship or Incorporation?—With the demise of the League of Nations the Union government held that there was nothing in the covenant that empowered it to transfer or delegate its powers, as regarded mandates, to any organization. In this contention South Africa was supported in 1950 by an opinion of the International Court of Justice, which held that the Union was under no obligation to place the territory under a United Nations trusteeship, but that on the other hand an obligation rested on South Africa to submit reports on the administration of the territory to the UN. In spite of pressure South Africa firmly refused to agree to the inclusion of the territory in the international trusteeship system but was willing to submit reports to Great Britain, the United States, and France as a matter of courtesy.

The proposal that South West Africa should be incorporated in, or should become a fifth province of, the Union arose in 1946 when the subject was referred to a series of tribal meetings and it was reported that the majority of Africans was in favour of the proposal, the Herero being the only substantial body against it. Later in the same year Gen. J. C. Smuts asked the United Nations that the territory be incorporated in accordance with the wish of its people, but the request was refused. The South African government did not press the demand but declared its intention, and this applied both to trusteeship and to incorporation, to continue to administer South West Africa in the spirit of the mandate. However, the association of the two countries, already close, was made much closer by the South West African Affairs (Amendment) Act of 1949 (see *Administration and Social Conditions*, below). The South African Citizenship Act of 1949 made it possible for those who had been "denaturalized" in 1942 to apply once more for naturalization. In 1955 a commission was appointed to consider the question of German language rights. Its report, produced in 1957, stated that the 20,000 German-speaking people, *i.e.*, 35% of the white population, wanted equal status for German with English and Afrikaans. A German-speaking person may address the South African state departments in German but cannot demand a reply in the same language. German is, however, fully recognized in the local Legislative Assembly.

The deadlock regarding trusteeship continued in discussions at the UN in the following years. A UN committee (appointed to consult with the South African government on a possible basis for agreement) suggested in its report in September 1958 that the territory might be partitioned. The northern portion of South West Africa, containing the great majority of the Bantu population, was to be administered by the South African government as an integral part of the Union under a trusteeship agreement with the UN, while the rest of the territory was to be annexed to the Union. The Union government announced that this did not mean that it had agreed to partitioning the territory but that it would be prepared to investigate the possibilities. However, the UN later rejected partition as a possible basis for agreement.

A deputy minister for South West Africa was appointed for the first time in August 1961. Debates on the future of the mandate continued in the UN. In 1964 the report of the Odendaal Commission of South West Africa was published. It recommended proposals for constitutional change, including extension of the principles of apartheid to South West Africa, and economic development with South African financial help. In 1960 Ethiopia and Liberia instituted proceedings in the International Court of Justice in which they asked the court to declare, *inter alia*, that the 1920 mandate was still in force and that South Africa had failed to fulfill its obligations under the mandate. In 1962 the court held that it had jurisdiction to adjudicate in the case, and in July 1966 it rejected the Ethiopian and Liberian complaints on the ground that these two countries had not established any legal right or interest in the subject matter of their claims. In October the UN General Assembly voted to end South Africa's mandate.

(Av. Sv.; X.)

Administration and Social Conditions.—*Government.*—In 1920 the Council of the League of Nations conferred on the British sovereign a mandate over the former German colony of South West Africa to be exercised by the governor-general of the Union of South Africa, who, by proclamation in 1921, delegated his powers to an administrator appointed by the Union government. After May 31, 1961, the state president of the Republic of South Africa exercised the mandate and delegated his powers to an administrator appointed by the government of the republic. An executive committee of 4 members (presided over by the administrator) and a Legislative Assembly of 18 members are elected as in the republic's provinces and with similar powers. (*See* South Africa, Republic of: *Administration and Social Conditions.*) In addition, the South West African Affairs Amendment Act, 1949, provides for six electoral divisions of the territory, each returning one representative to the South African House of Assembly, and for representation in the Senate by four senators, two of whom are nominated (one for the Coloured population).

Urban local government is undertaken by elected town councils and appointed village management boards, while rural administration is a matter for local magistrates. Windhoek is the seat of the administration. Administration of Bantu affairs (subject to the Native Urban Areas Proclamation, 1951, which followed the Union Native [Urban Areas] Act, 1945) was taken over by the South African Department of Bantu Administration and Development in 1955. Extensive Native reserves have been established in the rural areas.

Generally speaking, taxation accords with that of the Republic of South Africa, a state income tax having been introduced in 1942 and the old municipal income tax replaced by rates on property in 1920. The main sources of revenue are income tax, customs and excise duties, and mining taxation.

Living Conditions.—Machinery for regulating wages, registering labour unions, and settling disputes was established in 1953. There was full employment, and no unemployment benefit plans were found necessary. African labour is generally adequate, but in some cases there is a shortage. Housing for the white population is financed by building societies. In the African townships municipalities provide subsidized housing with state aid.

A report of the Special Committee on Colonialism, presented to the UN General Assembly in January 1965, alleged that foreign monopolistic combines operating in South West Africa were exploiting African workers, through restrictive contracts and conditions, in a way that amounted to virtual slavery. These allegations were denied by South Africa. African labour in the territory is regulated by masters' and servants' laws, pass laws, and influx control in the urban areas.

Health.—Health and hospital services parallel those of South Africa. Hospitals for whites are state aided and run by boards responsible to a director of health services. Hospitals for Africans are directly controlled and maintained by the administration.

Justice.—The judiciary consists of a High Court and circuit

courts (from which appeals lie to the appellate division of the South African Court) and magistrates' courts. The police and defense forces are incorporated in the South African forces.

Education.—Primary and secondary education is compulsory for all white children between 7 and 16 years of age, and German is a medium in some schools. The Cape syllabus and system are followed. Education of Coloureds and Africans is undertaken mainly by mission schools subsidized by the administration.

(L. H.)

The Economy.—*Agriculture.*—There is little crop cultivation in the territory except in the northern areas where the rainfall is just sufficient in most years for small crops of maize (corn) and kafir (sorghum), varying from about 30,000 to a few hundred thousand bags (of 200 lb.). Under irrigation a few thousand bags of wheat are produced, especially in the artesian valleys of the Nossob-Auob river system. The territory is mainly pastoral, with about 2,400,000 cattle, 3,000,000 karakul sheep, 700,000 other sheep, and about 1,500,000 goats. The pelts of the newborn karakul lambs are among the most valuable of the territory's exports.

Fisheries.—Sea fisheries are based mainly on Walvis Bay, with crawfish or rock lobster fishing mainly at Lüderitz. The pilchard is the all-important shoal fish. The fishing fleet includes about 100 well-equipped boats with diesel engines, echo-sounding devices, radio telephones, and radio direction-finders. The annual catch is about 600,000 to 700,000 tons. Whitefish and snoek are also taken in small quantities. At Walvis Bay there are seven factories for processing pilchards and three for whitefish and snoek, the fish meal and body oil being of more value than the canning product.

At Lüderitz six factories can rock lobster and produce meal and frozen tails, and one processes pilchards. Products of sealing on the offshore islands and at Cape Cross include annually about 10,000 pups (for furs), 3,000 wigs (skins of bulls), 25,000 pelts, and between 40,000 and 50,000 gal. of oil.

Mining.—The most valuable mineral is the diamond, which is found along the coastal strip and offshore between Lüderitz and the Orange River mouth. The principal fields are now the Oranjemund diggings, along the coast for about 60 mi. (100 km.) N of the Orange River. The annual production is about 1,500,000 k., of which about 98% are gem stones and 2% industrials, the value being about £30,000,000 ($84,000,000). From the Tsumeb mine the annual production of about 30,000 tons of blister copper, 45,000 tons of refined lead, 100,000 tons of lead, lead-vanadium, and lead-zinc ores, with 16,000 lb. of germanium dioxide, is valued at about £15,500,000 ($43,400,000). Tin and wolfram concentrates, from the vicinity of the Erongo Mountains and the Brandberg, vary in quantity from about 450 tons to about 1,500 tons, the value being about £400 ($1,120) a ton. Other minerals have much lower values: lithium about £15,000 ($42,000), beryllium £4,000 ($11,200), sillimanite £6,000 ($16,800). Salt is an important mineral from the coastal pans, the annual production of coarse and refined salt being about 100,000 tons, the value between £150,000 and £240,000 ($420,000 and $672,000).

Trade.—The bulkier items of export include, except for diamonds, the minerals mentioned above, the export being mainly from Walvis Bay, where 200,000 to 300,000 tons of ore and other minerals are shipped annually, mainly for European and American destinations. Karakul pelts are usually sent to the European auctions by air, their value generally exceeding £13,000,000 ($36,400,000) yearly. Fish products (canned, salted, fish meal, and oil) realize about £17,000,000 ($47,600,000).

To the Republic of South Africa the territory sends supplies of dairy products (butter and cheese) and cattle on the hoof. Imports include machinery, metal goods, building materials, manufactured goods, and oil. Of the cargoes landed at Walvis Bay the main commodities are gasoline, oil, timber, cement, and coal.

Finance.—In the 1950s and 1960s the territorial revenue fluctuated between about £15,000,000 ($42,000,000) and £20,000,000 ($56,000,000), the main items of revenue being income tax (most of which was paid by the mining companies and only about 10% by the non-Bantu inhabitants), customs and excise, and diamond export duty and profit tax.

Expenditure fluctuated during the same period between about £14,000,000 and £21,000,000, but these amounts included the annual appropriations to the Territorial Development and Reserve Fund, which varied between £7,000,000 and £20,000,000. Apart from these appropriations the main items of expenditure were: administration, education, public works, health, and posts and telegraphs. The net accumulated surplus in the territory revenue fund fluctuated between £1,000,000 and £7,000,000.

Communications.—The 1,453 mi. (2,338 km.) of railway line in the territory is all of 3 ft. 6 in. gauge. Coal-burning locomotives have been replaced by diesel. Of the 20,000 mi. (32,000 km.) of roads, 2,144 mi. are trunk roads, of which 500 mi. are tarred, 5,000 mi. are gravel-surfaced main roads, and 13,000 are district roads with varied surfaces. Road motor services include a bus route from the railhead at Grootfontein to the Angola border, and from Gobabis to Bechuanaland (Botswana). There are frequent air services between Windhoek and Keetmanshoop in the territory and Johannesburg and Cape Town, linking up with South Africa's international air services. The port of Walvis Bay, with an entrance channel 33 ft. (10 m.) deep, accommodates about 400 oceangoing vessels a year, with a gross tonnage of about 2,300,000. South West Africa is a member of the African Postal and Telecommunications Union. Telex services were introduced in 1956. There are radio-telephone links between point-to-point radio stations where the use of wire communication is uneconomical.

(J. H. Wn.)

SOUTINE, CHAIM (Haim) (1893–1943), Expressionist painter, was born in Smilovitchi, near Minsk in White Russia, the 10th of 11 children of a poor tailor. As a child he caricatured his family and neighbours. At the age of 16 he went to Vilna (Vilnius), where a friendly doctor helped him attend the school of fine arts for three years. In 1911 he emigrated to Paris and there met the sculptor Jacques Lipchitz and the painter Amedeo Modigliani, whose portraits he painted. In Céret and elsewhere in the south of France, he developed his characteristic style of painting with thick pigment and convulsive rhythms, twisting the human face and figure and tilting the forms of nature as in an earthquake. Though a leader of the Expressionist movement, he only admired earlier masters, especially Tintoretto, Rembrandt, and Gustave Courbet, whose compositions he adapted in certain famous canvases. He exhibited little during his lifetime, but his jewel-bright landscapes, studies of valets, cooks, and choirboys, and still-life paintings of poultry and carcasses of beef entered into French and American private collections and U.S. museums. While hiding in Touraine during World War II, he fell ill and was brought to Paris for an operation, where he died on Aug. 9, 1943. The Museum of Modern Art, New York City, exhibited his lifework in 1950, and 100 of his paintings were shown in the Galerie Charpentier in Paris in the summer of 1959.

SOUTSOS, ALEXANDROS (1803–1863), Greek poet, born in Constantinople, Turk., was the founder of the Greek Romantic school of poetry. He studied in Chios and later in Paris, where he was influenced by the French Romantics and by liberal political opinion. His verse satires, modeled on those of Pierre Béranger, are his liveliest writings and inspired the early development of modern political liberalism in Greece. His dramas and one long prose work, the *Exoristos* ("The Exile"), were considered

frigid and artificial, but his numerous lyrics were admired by his contemporaries in spite of their lack of originality and their rhetorical exuberance. Byron's *Childe Harold* was the model for his longest poem, *Periplanomenos* ("The Wanderer").

Soutsos' collected works were published in 1916.

See C. A. Trypanis, *Medieval and Modern Greek Poetry* (1951). (Ce. A. T.)

SOUZA BOTELHO, ADÈLE MARIE ÉMILIE FILLEUL, Marquise de (1761–1836), French writer of sentimental novels of a high moral tone, was born in Paris on May 14, 1761. Her mother was the wife of one of Louis XV's secretaries and may have been one of the king's mistresses. After the marriage of her sister Julie in 1767 to the marquis de Marigny (Abel Poisson, Mme de Pompadour's brother), Adèle in 1779 was married to the old comte de Flahaut (Alexandre de Flahaut de La Billarderie, 1726–1794). One of the many visitors to her salon, however, was Talleyrand, who was generally recognized to be the father of her son Charles, later celebrated as comte de Flahaut (*q.v.*). She went to England in 1792 (her husband stayed in France and died imprisoned by the revolutionaries), and published a novel, *Adèle de Senange* (1794), which had some success. Passing then to Switzerland, she attached herself to the duc d'Orléans (Louis Philippe, the future king of the French) and went with him in 1795 to Hamburg, where she had to work as a milliner. She returned to Paris in 1798. Married in 1802 to the Portuguese envoy José Maria, marques de Souza Botelho (1758–1825), she enjoyed some influence in society under Napoleon I. Later she helped in the education of the future duc de Morny (*q.v.*), the child of her son Flahaut and Queen Hortense. Her collected works, 6 vol. (1821–22), contained *Adèle* and six other stories. Her last work, a play, *La Duchesse de Guise*, was published in 1832. She died in Paris on April 19, 1836.

See A. de Maricourt, *Madame de Souza et sa famille* (1907).

SOVEREIGNTY. The concept of sovereignty, one of the most controversial ideas in political science and international law, is closely related to the difficult concepts of state and government, of independence and democracy. Originally, as derived from the Latin term *superanus* through the French term *souveraineté*, sovereignty was meant to be the equivalent of supreme power. It has departed, however, quite often from this traditional meaning.

Historical Development.—In 16th-century France, Jean Bodin (*q.v.*) used the new concept of sovereignty to bolster the power of the French king over the rebellious feudal lords; the transition from feudalism to nationalism was thus facilitated. The theories of John Locke at the end of the 17th century, and of Jean Jacques Rousseau in the 18th century, that the state is based upon a compact of its citizens, through which they entrust such powers to a government as may be necessary for common protection, led to the development of the doctrine of popular sovereignty that found expression in the American Declaration of Independence in 1776. (*See* Social Contract.) Another twist was given to this concept by the statement in the French constitution of 1791 that "Sovereignty is one, indivisible, unalienable and imprescriptible; it belongs to the Nation; no group can attribute sovereignty to itself nor can an individual arrogate it to himself." The idea of popular sovereignty exercised primarily by the people became thus combined with the idea of national sovereignty exercised not by an unorganized people in the state of nature, but by a nation embodied in an organized state. Going one step further and investigating who in the name of the people or of the state exercises sovereignty, John Austin (*q.v.*) came to the conclusion that sovereignty was vested in a nation's parliament. This was the supreme organ that enacted laws binding upon everybody else, but that was not itself bound by the laws and could change these laws at will. This particular description again fitted only a particular system of government, such as prevailed in Great Britain in the 19th century.

When this idea of legislative sovereignty crossed the Atlantic ocean, it did not really fit the American situation. The Constitution of the United States, being the fundamental law of a federal union, did not endow the national legislature with supreme power but imposed important restrictions upon it. A further complication was added when the Supreme Court of the United States asserted successfully its right to declare laws unconstitutional. While this development did not lead to a concept of judicial sovereignty, it seemed to vest the sovereign power in the fundamental document itself, the Constitution. This system of constitutional sovereignty was made more complex by the fact that the authority to propose changes in the Constitution and to approve them was vested not only in Congress but also in the several states and special conventions called for that purpose. It could be argued, therefore, that sovereignty continued to reside in the states or in the people, who under the terms of the 10th Amendment to the Constitution retained all powers not delegated to the United States by the Constitution or expressly prohibited by it. Consequently, the claims by the states' rights (*q.v.*) advocates that states continued to be sovereign were bolstered by the difficulty of finding a sole repository of sovereignty in a complex federal structure; and the concept of dual sovereignty of both the union and the component units found a theoretical basis. Even if the competing theory of popular sovereignty were accepted, vesting sovereignty in the people of the United States, it still might be argued that this sovereignty need not be exercised on behalf of the people solely by the national government, but could be divided on a functional basis between the federal and state authorities.

Another assault from within on the doctrine of state sovereignty was made in the 20th century by those political scientists (*e.g.*, Léon Duguit, Hugo Krabbe, and Harold J. Laski) who developed the theory of pluralistic sovereignty exercised by various political, economic, social, and religious groups that dominate the government of each state. According to this doctrine, sovereignty in each society does not reside in any particular place but shifts constantly from one group (or alliance of groups) to another. This pluralistic theory went even so far as to contend that the state is but one of many examples of social solidarity and possesses no special authority in comparison with other components of society.

Sovereignty and International Law.—While the doctrine of sovereignty has had an important impact on developments within states, its greatest influence has been in the relationships between states. The difficulties here can be traced back to Bodin's statement in 1576 that the sovereign who makes the laws cannot be bound by the laws he makes (*majestas est summa in cives ac subditos legibusque soluta potestas*). This statement has been often interpreted as meaning that a sovereign is not responsible to anybody and is not bound by any laws whatever. But closer reading of Bodin's writings does not support this interpretation. He emphasizes that even with respect to his own citizens a sovereign is bound to observe certain basic rules derived from the divine law, the law of nature or reason and the law that is common to all nations (*jus gentium*); as well as the fundamental laws of the state that determine who is the sovereign, succession to sovereignty, and limitations on the sovereign power. Thus Bodin's sovereign was restricted by the constitutional law of the state and by the higher law that was considered as binding upon every human being. In fact, Bodin discussed as binding upon states many of those rules that were later woven into the fabric of international law. Nevertheless, his theories have been used as justifying absolutism in the internal political order and irresponsible anarchy in the international sphere.

This interpretation was developed to its logical conclusion by Thomas Hobbes in the *Leviathan* (1651), in which the sovereign was identified with might rather than law. Law is what the sovereign commands, and it cannot limit his power; sovereign power is as absolute as men can make it. In the international sphere this condition led to a perpetual state of war, one sovereign trying to impose his will by force on all other sovereigns. This situation changed but little over the next two centuries; and sovereign states have continued to claim the right to be judges in their own controversies, to enforce by war their own conception of their rights, to treat their own citizens in any way that suited them, and to regulate their economic life with complete disregard for possible repercussions in other states.

During the 20th century important restrictions on the freedom of action of states started to appear. The Hague conferences (*q.v.*) of 1899 and 1907 established detailed rules governing the conduct of wars on land and at sea. The Covenant of the League of Nations (*q.v.*) restricted the right to wage war, and the Briand-Kellogg Pact of 1928 condemned recourse to war for the solution of international controversies and its use as an instrument of national policy. They were followed by the Charter of the United Nations (art. 2), which imposed the duty on member states to "settle their international disputes by peaceful means in such a manner that international peace and security, and justice, are not endangered," and supplemented it with the injunction that all members "shall refrain in their international relations from the threat or use of force. . . ." At the same time, however, the Charter listed as one of the basic principles of the UN "the principle of sovereign equality of all its Members."

In consequence of these developments, sovereignty ceased to be considered as synonymous with unrestricted power. In the first place, all states being equal, no state was allowed to impose its will upon another by the use of force. Sovereignty of each state became entitled to protection by the international community, as organized in the UN, against the designs of greedy neighbours; and the organization was authorized "to take effective collective measures for the prevention and removal of threats to the peace, and for the suppression of acts of aggression . . ." (*United Nations Charter*, art. 1). Though the means given to the UN to protect the sovereignty of its members were not sufficient to prevent all violations of national sovereignty and to settle all disputes by peaceful means, it cannot be doubted that important limitations have been imposed on the right of each state to do what it pleases in relation to other states. These limitations on the sovereignty of each state were balanced, however, by the increase in the freedom of each state from interference by other states. As far as matters essentially within the domestic jurisdiction of a state were concerned, each state regained that measure of internal sovereignty that had suffered so many actual restrictions in the period of constant use of force by one nation against another. Only to the extent that use of force has been effectively restricted was it possible for a state to expect that its personality, territory, and political independence would be properly respected, and that it would be able to enjoy unmolested the rights inherent in its external sovereignty.

It is, therefore, in the interest of every state that all the other states should comply faithfully with all those international obligations that safeguard its sovereignty. A state cannot, however, expect such compliance unless it reciprocally fulfills in a scrupulous manner all its obligations to other states. Those obligations are derived from principles of customary law developed painstakingly over several centuries, and from hundreds of treaties that are concluded every year.

Consequently, states have accepted a considerable body of law limiting their sovereign right of acting as they please. Those restrictions on sovereignty are usually explained as deriving from consent or autolimitation, but it can be easily demonstrated that in some cases states have been considered as bound by certain rules of international law despite the lack of satisfactory proof that these rules were expressly or impliedly accepted by them. On the other hand, new rules cannot ordinarily be imposed upon a state, without its consent, by the will of other states. In this way a balance has been achieved between the needs of the international society and the desire of states to protect their sovereignty to the maximum possible extent.

Nonsovereign States.—The 19th-century distinction between fully sovereign states and several categories of less sovereign units lost its importance under the law of the United Nations. Emphasis was placed not on legal differences among colonies, protected states, protectorates, and states under the suzerainty of another state, but on the practical distinction between self-governing and nonself-governing territories. Nonself-governing territories became under the charter of the UN "a sacred trust," and the states administering them promised to develop them towards self-government. Some of these territories were placed under a UN trusteeship that resulted in a closer supervision of their administration by the UN and in their speedier progress toward self-government or independence. Once a territory achieved self-government, as defined in resolutions of the general assembly, supervision by the UN ceased, even though independent status was not reached. This happened, for instance, when Puerto Rico achieved the status of a self-governing commonwealth in 1953.

Conclusion.—The concept of absolute, unlimited sovereignty did not last long after its adoption, either domestically or internationally. The growth of the democratic form of government imposed important limitations upon the power of the sovereign and of the ruling classes. The increase in the interdependence of states restricted the principle that might is right in international affairs. The peoples of the world have recognized that there can be no peace without law, and that there can be no law without some limitations on sovereignty. They have started, therefore, to pool their sovereignties to the extent needed to maintain peace; and sovereignty is being increasingly exercised on behalf of the peoples of the world not only by national governments but also by organs of the world community. Thus the theory of divided sovereignty, first developed in federal states, has become applicable also in the international sphere.

SOVETSK (formerly TILSIT), a town in Kaliningrad Oblast' of the Russian Soviet Federated Socialist Republic, U.S.S.R., stands on the left bank of the Neman River about 35 mi. (56 km.) from its mouth. Pop. (1959) 31,941. A castle was founded there by the Teutonic Knights, and the associated settlement became a town in 1552. In 1807 Napoleon and the emperor Alexander I signed the Treaty of Tilsit on a raft moored in the river. The town passed with northern East Prussia to the U.S.S.R. in 1945 and was renamed Sovetsk. It is an important rail junction, with lines to Kaliningrad, Chernyakhovsk, Poland, Klaipeda, and Riga. The chief industry of Sovetsk and of its twin town, Neman, a few miles upstream, is papermaking. (R. A. F.)

SOVETSKAYA GAVAN, a town and seaport of Khabarovsk Kray of the Russian Soviet Federated Socialist Republic, U.S.S.R., stands on the mainland, on the southeastern shore of a deep, narrow gulf of the Tatar Strait (the strait separating the mainland from the island of Sakhalin, just north of Japan). Pop. (1959) 50,421. Although the bay, which forms one of the best natural harbours of the Soviet Far East, was discovered in 1853 by Lieut. N. K. Boshnyak, its first development began only on the eve of World War I, and town status was not achieved until 1941. Great impetus was given when it became the terminus of a railway from Komsomolsk, and it is now the second Russian port of the Pacific coast. Fishing, fish canning, and timber working are important. (R. A. F.)

SOVIET (Russian, "council"), a policy-making and administrative agency established at various levels of government in the Union of Soviet Socialist Republics under the direction of the Communist Party.

Soviets were organized in 1905 by Marxist-stimulated intellectuals in Russian cities as strike committees to coordinate worker opposition to tsarist policies. Suppressed after the 1905 revolution, soviets of workers and soldiers were reestablished by left-wing political leaders to influence governmental policy on the tsar's abdication in March 1917. Lenin demanded that they assume power when he returned from exile in April 1917. A national federation of soviets was created in June 1917, but moderate leftists held control until November. After seizure of power Lenin turned to a congress of deputies of local soviets to provide a semblance of popular support for Bolshevik leadership. By the spring of 1918, he had control, and thereafter the various soviets became unchallenged instruments of Bolshevik policy.

Structurally, soviets were large assemblies elected at village, city, county, province, republic, and all-union levels. From 1917 to 1936 the franchise was denied employers of labour for profit, private merchants, *rentiers*, priests, and monks.

The 1936 constitution opened the franchise to all on secret ballot, but in practice the one-candidate election was continued, permitting citizens only to accept or reject candidates nominated by professional groups under Communist Party direction. Soviets chose executive committees, called councils of ministers, at republic and all-union levels, to supervise administrative departments.

Local soviets operated public housing, local transportation and industry, schools, and health facilities. Republic and all-union soviets approved economic plans and budgets. No critical debate or adverse votes occurred because deputies were largely Communist Party members bound to resolve disputes privately. *See* also UNION OF SOVIET SOCIALIST REPUBLICS: *Administration and Social Conditions.*

SOVIET LAW is a system of public order devised by Communist politicians after the Russian Revolution of 1917 and emulated subsequently in Asian and eastern European states where Communist parties became dominant. Although it was classified by some legal scholars as a subdivision of the Romanist or civil-law system, its adherents claimed independent status for it. This claim was recognized in practice after World War II by election to the International Court of Justice of judges representative of the Soviet legal system in accordance with requirements of the International Court's statute (art. 9) that it include judges representative of the main forms of civilization and of the principal legal systems of the world.

HISTORY

Origin.—Since Karl Marx and Friedrich Engels prescribed no pattern of law for a state organized to achieve the aims set by their *Communist Manifesto* of 1848, it was left for Lenin and his colleagues in the Russian Communist Party after the Bolshevik Revolution of 1917 to improvise a legal system. General guides provided by Marx and Engels were that law be regarded as an instrument of the state, not as a limitation upon those who make policy, and that it enunciate rules of public order facilitating the transition to Socialism and ultimately Communism. Its major tasks were to be two: (1) elimination of the political power of the *bourgeoisie* by depriving them of their ownership of productive resources; and (2) education of citizens in the disciplined pattern of life claimed by Communists to be requisite to achievement of the social order they desired. Completion of these two tasks would, in the Communist view, assure abundant production suitable to realization of the Communist aim of distribution according to need and also the self-discipline of citizens necessary to make coercion unnecessary in preserving order. The police, the army, and courts would become unnecessary, and law would in Marxist terminology "wither away." Citizens would perform social obligations, expressed in morals and unsanctioned administrative regulations, out of conviction of their desirability rather than out of fear of punishment for their violation.

The new principles were embodied in the first constitution of the Russian Soviet Federated Socialist Republic, promulgated July 10, 1918 (art. 9), as follows:

> The basic task placed during the present transitional moment on the constitution of the R.S.F.S.R. is the establishment of the dictatorship of the city and village proletariat and of the poorest peasantry in the form of a powerful all-Russian Soviet authority with the objective of complete suppression of the *bourgeoisie,* the exploitation of man by man and the installation of socialism, under which there will be neither division into classes nor a State authority.

Lacking any precise pattern for a legal system designed to achieve the purposes stated in the first constitution, the new government issued only a few decrees designed to establish a framework for a new society and a primitive institutional structure to enforce it. The decrees deprived private individuals of the ownership of land, banks, insurance companies, merchant fleets, and large-scale industry in implementation of the policy of expropriation of the *bourgeoisie;* created restrictions on the employers of labour; and secularized marriage and divorce. The enforcement instruments, called "people's courts," operated like tribunals in a tribal society, without benefit of professional prosecutor or bar.

To permit regulation of the multitudinous social relationships for which no new law was prescribed, judges were directed at the start to apply Russian imperial laws, but only to the extent that they had not been revoked by the Revolution and were not contrary to the revolutionary conscience of the judges. Perhaps because Lenin and his colleagues were too busy to do otherwise, or perhaps because they preferred to let develop in practice a new legal order, no all-inclusive systematized body of law was prescribed until 1922. Local judges were guided during the first years, apart from the basic decrees indicated, only by suggestions issuing from the people's commissar of justice in the form of instructions, procedural manuals, and journal articles praising some court decisions as the proper application of revolutionary conscience and denouncing others as improper.

Political enemies of the Communists were not brought before the courts but were condemned by political bodies created at the same time as the people's courts and called revolutionary tribunals, or they were arrested and imprisoned without public hearings by the political police (Cheka). Lenin and his jurists professed only temporary resort to treatment of opponents outside the regular court system. Nevertheless, the conduct of revolutionary tribunals and of the Cheka greatly influenced the course of Soviet law long after their formal abolition in 1922, for they stimulated lack of respect for formality and strict adherence to law even among those charged with enforcing and administering the law.

New instrumentalities emerged within the Ministry of Internal Affairs (MVD), under the personal dictatorship of Lenin's successor, Joseph Stalin, to rid him of opponents. Following the latter's death in March 1953 the Communist Party's first secretary, N. S. Khrushchev, disclosed that many innocent persons had been convicted and sentenced to long prison terms and even to death by special boards of the MVD. The Soviet method of preserving order was revealed officially to have been dual, with courts on one side dealing publicly with nonpolitical offenses and social disputes, and administrative boards and the security police punishing secretly on the other side those whom Stalin chose to call his enemies.

Codification.—Reintroduction of private enterprise in limited areas and subject to strict controls followed the declaration, in 1921, of the New Economic Policy (*see* UNION OF SOVIET SOCIALIST REPUBLICS: *History*) aimed to speed reconstruction to overcome the devastating effects of world and civil war. This reintroduction necessitated, in the Communist view, stabilization of law if capitalists were to be induced to invest. Lenin's commissar of justice, D. I. Kurskii, considered these measures retrogressive but necessary, while N. V. Krylenko, later to become federal commissar of justice, called them the natural evolution of five years of Soviet law. Whatever their origin, stabilization efforts took form in the first systematic codification, and a complex institutional framework of courts was constructed.

A judiciary act of Oct. 31, 1922, established within the Russian republic a three-stepped system of general courts with civil and criminal jurisdiction.

1. The name people's court was retained for the lowest level, but the institution was less primitive than that of 1917. Its bench comprised a full-time judge appointed annually and two lay judges selected for service of a few days in rotation from a panel of intelligent and politically trustworthy citizens. Lay judges shared responsibility with the professional judge in deciding issues of law and fact.

2. Appeals from this court lay to a new provincial court evolved from the Congress of People's Judges which, under the prior rules, had gathered periodically in each province to survey the work of the local courts. The provincial courts also received jurisdiction to try offenders against the security of the regime and other serious civil and criminal cases. As an appellate court the provincial court presented a bench of three professional judges. As a trial court it was composed like the people's court, except that the lay judges were selected from a panel of more experienced and politically sound citizens.

3. To coordinate policy in all provinces there was created the Supreme Court of the republic, evolving from a control department established earlier in the Commissariat of Justice. This court was authorized not only to hear appeals from cases tried in provincial courts but also to discipline lower courts, issue rulings interpreting the codes, and even to try cases of an unusually important character.

To provide specialized treatment of crimes relating to military matters and to the disruption of transport, then deemed critical to the success of the regime, special courts which had evolved earlier were continued by the judiciary act and subordinated to the Supreme Court. An office of public prosecutor and a college of defenders to perform the functions of a bar were established to aid the judges, following experimentation with institutions designed to conduct prosecution and defense on a nonprofessional basis.

Substantive law and procedure to be applied by the new courts were established by codes enacted throughout 1922 and early in 1923, these being criminal, civil, family, land, and labour codes and also codes of criminal and civil procedure. Drafters of these codes followed patterns essentially similar to those of the Romanist states of the European continent.

Patterns of legal institutions and substantive and procedural law enacted by the R.S.F.S.R. were copied with little variation in the other Soviet-type republics that had emerged in peripheral regions of what had been the Russian Empire. Federation of the Soviet republics into the Union of Soviet Socialist Republics on Dec. 30, 1922, caused no change in the judicial system except the establishment, as a coordinator of all practice, of a supreme court of the U.S.S.R. The first federal constitution, adopted provisionally on July 6, 1923, and permanently on Jan. 31, 1924, extended authority to the federal government to enact general principles of law to be followed by the republics in maintaining their codes. While this development might have caused a change in the Soviet legal system, it did not; the first federal judiciary act of Oct. 29, 1924, confirmed the system of courts then existing in each of the republics, and no change was made in substantive or procedural law. The sole innovation was that the military and transport courts were placed under sole control of the Supreme Court of the U.S.S.R.; thus was created a self-contained system of federal courts, with lower branches functioning throughout the republics but beyond the reach of republic officials. A sharp line was thus drawn between courts dealing with matters vital to the security of the regime and those concerned with social disputes.

The pattern established for Soviet courts and codes of law in 1922 and 1923 continued until Stalin's death, although the second federal constitution of Dec. 5, 1936, transferred authority to the federal level to enact codes of law to replace those of the republics. Although a second federal judiciary act was issued on Aug. 16, 1938, new codes were not enacted. On Feb. 11, 1957, the constitution was amended to restore the original relationship between republics and federation, namely that they enact their own codes but conform to general principles established federally. The first of the new general principles were enacted for criminal law and procedure on Dec. 25, 1958; for civil law and procedure on Dec. 8, 1961. Others were enacted at intervals thereafter, and republic codes were revised subsequently. The major innovation of the 1958 enactments was the requirement that punishment be ordered only by a court in accordance with the rules of the procedural code. This provision was heralded by Soviet jurists as preventing return to extralegal procedures such as those exercised by the MVD during Stalin's dictatorship.

CHARACTER OF SOVIET LAW

Source.—Montesquieu's concept of separation of powers as embodied in the Constitution of the United States of America was rejected by the founders of the Soviet legal system. The legislature was made supreme over the executive and the judiciary. In principle only the legislature's enactments were a source of law.

Practice made the executive a source of law, however, for the Council of Ministers often acted without convening the legislature. The second federal constitution of 1936 attempted to stop this practice in violation of the constitution of 1923, but the executive soon again usurped legislative authority. The post-Stalin reforms again sought to restore monopoly lawmaking power to the legislature. In practice it was not the legislature in full assembly but its derivative body, the presidium, elected from its membership to legislate during intervals between full sessions, that created the day-to-day changes in law. Although subsequent ratification from the full body was sought, revocation of presidium action was virtually impossible because of passage of time. The presidium thus became the most active source of law, except for the state economic plan, the budget, and enactment of general principles for republic codes.

Communist Party orders were in the technical sense not a source of law, for to be binding on courts these had to be enacted by state agencies. Still, the party provided the initiative for legislative action. Some vital laws, such as those reforming agriculture or industry, were given preeminent status by signature by the party secretary as well as by the chairman of the presidium when they were published as law.

Having rejected judicial lawmaking with assertion of the legislature as the sole lawgiver, Soviet jurists accepted no concept of judicial precedent like that of the Anglo-U.S. common law. Nevertheless, the Supreme Court of the U.S.S.R., in exercise of its authority to enunciate principles of interpretation based upon examination by its full body of a course of judicial practice, proclaimed such far-reaching principles as to make of these a source of law. Even individual decisions of the Supreme Court, although lacking the authoritative force of the general rulings, were given careful attention by lower courts, since they were published as guides. The Soviet legal system in practice adopted much the same approach to judicial decisions as have Romanist systems generally.

The Supreme Court of the U.S.S.R., being subordinate to the legislature, had no right to declare a law unconstitutional nor to create any limitation upon the legislature or the executive on the ground that some higher or general principles of law had been violated.

Control over the judiciary was preserved for the legislature at all levels above the people's court by giving it appointive and recall power, through the soviet operating at the court's level. Only people's judges were elected by the people under provisions introduced by the 1936 constitution, although elections were not begun until after World War II. Elections followed the pattern established for all representative bodies in the U.S.S.R. by Stalin, namely the one-candidate ballot, the candidate being chosen by local professional groups with the guidance of the Communist Party members in the groups. In practice, judicial decisions had to accord generally with Communist Party policy or the judge risked recall.

In light of the foregoing, the constitutional provision that "judges are independent and subject only to the law" (art. 112) had to be understood as denying to local officials the right of intervention in the formation of an individual decision on personal grounds, but as not prohibiting Communist Party intervention when such intervention was properly formulated in criticism of a line of decisions out of keeping with party wishes.

Judges were not deprived entirely of initiative by the rule of

legislative supremacy or by the leading role played by the Communist Party. In both the civil and criminal codes adopted in 1922 there was authorization to depart from the rigid provisions of the code under special circumstances. The civil code opened with art. 1, reading, "Civil rights are protected by law except in cases where they are exercised contrary to their social and economic purpose." This rule permitted judges to apply their concept of state policy, when it was not specifically stated, to achieve an appropriate result in a given situation, but the decision created no rule of law for future cases. The article was used frequently to justify judicial refusal to protect the rights of capitalists during the period of reconstruction (1922–28), but after 1930 it fell into disuse. Soviet jurists argued for its deletion from the code as unrelated to a stable society from which all capitalist elements had been eradicated, but it was retained in the civil-law general principles of 1961 (art. 5).

The criminal code of 1922, and as revised in 1926, permitted the judge to exercise discretion not only in withholding conviction where a crime had clearly been committed, provided that he found no social danger, but also in punishing a citizen who had committed no crime defined as such by the code. The formula for such judicial initiative was that the act be found socially dangerous in a manner analogous to another act specifically defined as a crime. This provision, which led to unpredictability, was eliminated from the criminal law by the general principles adopted in December 1958.

Substantive Provisions.—Soviet jurists claimed uniqueness for their system because of its constitutionally defined function of promoting socialism. The end, in their view, transformed the means.

Civil Rights.—Civil rights as defined in the U.S.S.R. Constitution of 1936 (ch. x) provided the primary example of the Soviet approach. Guarantees of freedom of speech, press, and assembly were limited to such exercise as might strengthen Socialism (art. 125). Judicial practice indicated that speech evoking hostility to Soviet authority on grounds of disagreement with the elements of social order declared by the constitution as fundamental to Socialism—such as state ownership of the productive resources, collectivization of agriculture, the one-party political system, and equality of races—was punished as a crime against the state if intent to disrupt the system was found. In the practice of the security police prior to the death of Stalin, disruptive intent was presumed from social origin (as a prerevolutionary landowner, industrialist, merchant, army officer, or priest, and sometimes in children of such persons).

State Enterprise.—Among the various fundamentals of Socialism, primary place was given to state ownership of productive property, and law codes reflected this emphasis in various provisions. The criminal code established more severe penalties for theft or destruction of state property than for that of personal property. The labour code was concerned with state employment. The provisions of the civil code of 1922 governing incorporation of private businesses became obsolete with the passing of the New Economic Policy, and even those provisions relating to sales, contracts, property damage, and inheritance governed only a small segment of social activity because the volume of personal property relationships was sharply reduced. Nothing monopolized by the state could be sold or leased by private persons or even by state enterprises and cooperatives, with limited exception for land allocated to peasant households disrupted temporarily by war or industrial employment.

A major new area of law that accompanied Socialism was the law governing state enterprise. Its task was to provide the order and accountability required for performance of the national economic plan. After experimentation for a period with direct operation by ministerial departments, state enterprise passed in 1923 to newly created public corporations, having juridical status with power to sue and be sued. State property was assigned to each enterprise, and business-type accounting procedures were introduced to assure strict accountability. The function of law in the accountability process was performed by an adaptation of the principle of contract. Interrelations of public corporations took the form of written agreements to buy, sell, and perform services, these agreements being executed in performance of the planned objective of each corporation.

For scarce commodities, such as aluminum, copper, and steel, the plan was detailed, establishing the precise corporations to produce and consume the materials. Contracts in such cases became documentation of detail in implementation of planned relationships; management had no choice but to execute the contract. With regard to less critical commodities, the plan provided no such detail of corporate interrelationship; management was permitted to seek out parties producing needed raw materials and to enter into relations with distributing units prepared to sell its products to ultimate consumers. With the administrative reform of 1957, which abolished many centralized ministries and substituted regional economic councils to guide the economy, the area of relatively free choice in the establishment of productive relationships among public corporations was enlarged, and contracts took on greater meaning as the documentation of relationships established with some exercise of free will by the parties. Nevertheless, the aim of plan performance was dominant, and a party evidencing reluctance to make a contract with another could be taken before a state agency for determination of the necessity of execution.

The state agency designated to hear precontract disputes as well as those arising over failure of performance was a specialized court designated as "state arbitration." Created on various levels to facilitate quick response to demand for a decision, its arbitrators utilized the law of the civil code in reaching a decision, but more than money damages was required. Since the primary purpose for the contract relationship was execution of the plan, arbitrators were directed to assure specific performance, if possible, and only if that were out of the question, to order the payment of damages; such payment set in balance the profit and loss statement of the injured party and attracted the attention of state inspectors to the offending party by upsetting its profit and loss statement.

Personal Property and Personal Injury.—Provisions of the civil code relating to personal property matters of private citizens, as well as to personal injury actions, provided no surprises for those familiar with the Romanist provisions of the civil codes of the European continent. There was nothing Socialist about these provisions, although Soviet codifiers sought to incorporate some hardship provisions to avoid exploitation of the poorer party to a bargain. Such a provision, already in use even in western Europe, was the one prohibiting enforcement of a contract if one party in negotiating it had taken advantage of the "extreme want" of the other. Likewise, uneconomic maintenance of a dwelling could result in its confiscation by municipal authorities if the owner had resources to make repairs and had been notified of the necessity of repair at an appropriate time.

Labour.—The provisions of labour law reflected state ownership of productive resources, especially after 1936, when the second federal constitution prohibited private employment from which a private citizen anticipated a profit as entrepreneur. Labour law then came to resemble civil-service law in many non-Soviet-type states, its distinguishing feature being that it was the law of all employment rather than of a small segment. Statutes established wages and hours in accordance with a system of standard classification of all jobs. Employers were not permitted to depart from the standards after 1938.

The labour code defined circumstances under which dismissal was permitted (art. 47), such as incompetence, malfeasance, termination of a position, or unauthorized absence for a given period of time. In regard to unauthorized absence, the period was changed as discipline became stricter with the approach of World War II, until finally dismissal was eliminated as a sanction and by law of June 26, 1940, workmen were subjected to criminal prosecution if absent without authorization for more than 20 minutes. After Stalin's death the provision was repealed by law of April 25, 1956. A labour grievance procedure comprising tribunals on which representatives of management and the labour union shared equally in the decision provided a preliminary opportunity for an aggrieved employee to contest management action. A dissatisfied employee might proceed to court in appeal of the tribunal's deci-

sion unless he was a supervisor or in a position requiring security check.

Collective agreements between management and labour unions fell into disuse in the mid-1930s, when wages and hours became fixed by statute, but they were reintroduced in new form in 1947. They then became instruments to stimulate production by restating workers' obligations and assuring distribution, in accordance with the workers' desire, of the bonuses granted by statute to employees for exceeding planned quotas or reducing costs of production. Labour unions were not deprived specifically of the right to lead strikes, but Communist Party leaders in 1928 declared strikes unthinkable as being against the workers' own state.

Land.—Land use was governed by the land code of 1922, by supplementary decrees, such as the Model Charter for the Collective Farm as enacted initially in 1930 and subsequently amended, and by specialized decrees on the use of land by public corporations and individual houseowners. In accord with Socialist tenets, title to land remained in the state and only the use was allocated. Use passed in perpetuity to the individual houseowner, peasant household, collective farm, or public corporation, subject to withdrawal in the event of misuse or requirement for other state activity such as railroad or highway construction. Safeguards against arbitrary withdrawal of farmlands were instituted, it being the desire of policy makers to preserve the psychological advantage provided by capitalism in encouraging maintenance and improvement of land held in perpetuity. No sale or leasing of perpetual right to use was permitted, except as already indicated.

Family.—Family law provided for secularization of marriage and divorce. Early law permitted registration of divorce at the request of one spouse and without notification to the other, but this procedure was replaced in 1944 by a stricter system thought to be in keeping with Engels' dictum that Socialism would see the introduction of the truly monogamous family. Thereafter, the people's court was obligated to attempt reconciliation, and only in the event of failure could a party proceed to the provincial court, which was required to satisfy itself that restoration of the marriage relationship was impossible before granting the divorce. (*See* also MARRIAGE, LAW OF: *Europe;* DIVORCE: *Europe.*)

Procedural Law.—Romanist influence was strong in the codes of criminal and civil procedure, which copied the main features of the French codes, although retaining more possibilities of control by the state (*see* FRENCH LAW).

Emphasis in criminal procedure was placed on investigation before trial, as in French practice. The examiner had to establish more than a prima-facie case required of the grand jury in the traditional common-law system. The suspect had to be given an opportunity to testify and to produce witnesses and evidence in his defense. The examiner became a preliminary judge authorized to bring the case to trial only if he became convinced of guilt, so that the public trial consisted primarily of verifying the examiner's work rather than hearing the defendant's case for the first time. Contrast with the French model was provided by the fact that the examiner was not a magistrate but subordinate to the office of prosecutor, and until 1958 no attorney was permitted the defendant during the preliminary investigation. Even thereafter only juveniles were given an absolute right to an attorney.

Trial procedure followed the French model closely in that the judges were instructed to establish their intimate conviction of guilt. To do so they might go beyond evidence presented by the prosecution and defense. The court might call witnesses, seek its own experts, examine material evidence, and visit places connected with the crime. The judges did most of the interrogating in the courtroom, relying on the prosecutor and the defense only to bring out points overlooked. No rule of evidence of any kind bound the court, except the rule of relevance.

Civil procedure required observance of rules of evidence only for certain formalities established by the civil code, such as those for documents like contracts or wills. Otherwise, the judges were as free in civil as in criminal matters to seek or hear what they desired to establish their intimate conviction. Soviet jurists claimed an innovation in the prosecutor's authority to intervene in a civil case at any stage thought necessary to the interests of society. This sometimes brought in the prosecutor to protect a party whose attorney appeared incompetent.

Appellate courts finding violation of procedural requirements, of substantive law, or unconvincing evidence were required to remand for new trial. Revision of a sentence or of a decision without retrial in a court of original jurisdiction was permitted only when the original court had no jurisdiction, where an amnesty had been improperly applied, or where there had been no basis for trial at all. A penalty could not be increased on defendant's appeal.

A singular feature of Soviet procedure was the authority given to Supreme Court presidents and to the prosecutors of the republics and of the U.S.S.R. to protest a decision, whether civil or criminal, after it had become final on appeal or in absence of appeal. This procedure permitted reopening of convictions or even of acquittals if the highest legal authorities found grave error in their periodical audit of inferior-court activities. Prosecutors frequently requested such reopenings, even of convictions obtained by inferior prosecutors. This created the opportunity of petition to superior prosecutors or to court presidents after all remedies as of right had been exhausted. At the same time it gave state authorities a second chance, not given the convict or the party to a civil suit, to change an otherwise final decision.

PEOPLE'S DEMOCRACIES

Application of the pattern of law evolved within the U.S.S.R. to other areas began when Outer Mongolia declared establishment of its "people's government" on July 11, 1921. Mongolia was then a nomadic society without industry. Nationalization of productive resources had little effect on nomadic life, an exception to nationalization being made in the area of primary concern, namely the private ownership of cattle herds. Nevertheless, the base was laid for following Soviet legal patterns in the first constitution of the Mongolian People's Republic promulgated on Nov. 26, 1924. Thereafter, state-owned industry was developed after Soviet patterns, and following adoption in the U.S.S.R. of the second federal constitution, a second Mongolian constitution was promulgated on June 30, 1940. Its provisions on courts and prosecutors were like those of the U.S.S.R., and the subsequently adopted law on land use of Feb. 6, 1942, provided the same formula of state ownership of land allocated for use gratis and in perpetuity to the nomadic herdsmen for their privately owned cattle. A labour law of Feb. 14, 1941, followed the Soviet pattern, as did a social insurance law of June 22, 1942.

The major opportunity to install the Soviet legal system outside the U.S.S.R. came only after World War II, when Soviet-type governments were created for European states occupied by the Soviet army in pursuit of retreating German forces. The system was also established in China, North Korea, and North Vietnam as military victories placed the Communists in power. In each country there was some variation, related to the degree of economic development, from the Soviet pattern evolved in the U.S.S.R.

Eastern European states permitted retention of limited forms of private enterprise in industry and agriculture reminiscent of the economic pattern of the U.S.S.R. during the 1920s. In China, capitalists, except for landlords, were permitted for a time to function widely, though subject to strict state controls and heavy taxation. In North Vietnam even private landowning was permitted except for large estates, which were divided and distributed among tenants and poor peasants. Law in these communities reflected the presence of capitalist elements in the economies. Yet in all the people's democracies the banks, large-scale industry, insurance, mining, and transport were nationalized and monopolized by the state. Law relating to this sector of the economy, termed the socialized sector, followed the U.S.S.R. model.

Throughout all the states that became Communist, law was given the functions previously established in the U.S.S.R. Thus, the constitution of the Hungarian People's Republic of Aug. 20, 1949, declared (art. 41):

> Courts of the Hungarian People's Republic punish enemies of the working people, defend and secure the state, economic and social

structure of the people's democracy, its offices and the rights of the toilers, educate the toilers in the spirit of observance of the rules of socialist intercourse.

Regulations governing the organization of the people's courts in the People's Republic of China, promulgated Sept. 3, 1951, specified that courts were "to consolidate the people's democratic dictatorship, uphold the new democratic social order and safeguard the fruit of the people's revolution." The People's Republic of Bulgaria was even more outspoken than the U.S.S.R. in clarifying the function of law; in its constitution of Dec. 4, 1947, it granted the right to citizens to create associations, but (art. 87) only "if they are not directed against state and public order established by the present constitution," and then stated:

It is forbidden and will be punished by law to form organizations having as their purpose taking from the Bulgarian people the rights and freedoms won by the people's uprising of Sept. 9, 1944, and guaranteed by the present constitution, or to limit these rights and freedoms, to place under threat the national independence and state sovereignty of the country or to propagate open or concealed fascist or antidemocratic ideology, or to facilitate imperialist aggression, and also to participate in these organizations.

The Chinese Communist Party leader, Mao Tse-tung, in his 1949 speech "On People's Democratic Dictatorship" indicated that he had adopted in effect what had been Stalin's interpretation, enunciated in 1930, of the Marxist concept of the withering away of the state. Mao declared that there could be no withering in China as long as there was opposition to the state. The constitution of the People's Republic of China, promulgated on Sept. 20, 1954, nearly five years after proclamation of the people's republic on Oct. 1, 1949, fixed as final the system of courts evolved in emulation of those of the U.S.S.R. There were to be lay assessors, full-time professional judges, Soviet-type prosecutors, and three levels of courts; "judges were independent and subject only to the law," as they had been declared to be in the U.S.S.R. constitution.

Judicial patterns of the same type were established in the constitutions of the other people's democracies: the Democratic People's Republic of Vietnam (Nov. 8, 1946); the People's Republic of Albania (March 14, 1946); the Rumanian People's Republic (April 13, 1948, and Sept. 24, 1952); the Republic of Czechoslovakia (May 9, 1948); the Democratic People's Republic of Korea (Sept. 8, 1948); the German Democratic Republic (Oct. 7, 1949); and the Polish People's Republic (July 22, 1952).

The applicable law was stated in a small number of specific decrees in each republic, but otherwise determination of law was left to the judges. The Chinese government, among its first actions, abrogated all legal codes of the prior government. In October 1950 the Chinese premier, Chou En-lai, listing the documents to serve as guides to the judges, included not only specialized decrees of the government but also the Common Program of the Chinese Communist Party.

The provisional regulations on people's courts of 1951 (art. 4) read, "Where no regulation is applicable, the policy of the Central People's Government will be adhered to." A law codification commission was established in the spring of 1950, but no basic codes emerged, only specialized statutes such as the land reform law of June 28, 1950; the law on marriage, April 13, 1950; the law on questions of employment, July 25, 1952; and the organic law for the court system, Sept. 21, 1954.

The Soviet-type states in eastern Europe moved more rapidly toward codification than had China, and in contrast to China confirmed the existence of prewar civil codes, although with modifications. Poland adopted a General Statute on Civil Law with 119 articles on July 18, 1950. As in the Soviet civil code of 1922, the codifiers sought to avoid possible injury to working-class elements; art. 3 provided: "It is forbidden to use one's rights to violate the fundamentals of socialist intercourse of the people's government." A Polish family code was adopted on June 27, 1950, and a decree on planned contracts on April 26, 1950.

Prior to the expulsion of the Yugoslav Communist Party from the Cominform on June 28, 1948, Yugoslavia, under the constitution of Jan. 31, 1946, had followed the Soviet legal pattern. Under Tito, Yugoslavia accepted the concept of monopoly of power in a Communist Party and the necessity of state ownership of productive resources, but refused to accept dictation from the Soviet Union on every detail, especially on centralization of industrial control and the speed of collectivization. The Yugoslav government experimented with bringing workmen into the managerial process of public corporations and in broadened autonomy for local government councils. Yugoslav legal philosophers rejected the view that the state could not begin to wither away until full achievement of Communism; they wanted to start relaxation of coercion immediately. Stalin's attempts to unseat Tito failed, and on Stalin's death his successors attempted reconciliation for a time, indicating acceptance of the idea that there could be many roads to Socialism.

Stalin's death in 1953 and his repudiation by the Communist Party of the Soviet Union at its 20th Congress in 1956 opened a new era in the law of Communist-led states. The People's Democracies sought to be relieved of Soviet tutelage. Risings in Hungary and Poland forced the Soviet leaders to acquiesce in the evolution of divergent legal systems. Polish jurists, including Communists, demanded humanistic attitudes toward legal procedure, and other east European states followed their lead. Even Soviet legal philosophers in 1958 endorsed a new humanism and declared it always to have been fundamental to Lenin's thought.

Only Chinese Communists resisted the trend toward strengthened legal procedures, denouncing Soviet policies of humanism and legality in an open letter published in 1963. Since 1957 Chinese leaders had abandoned their policy of copying Soviet legal patterns and had ceased efforts to draft codes of law, declaring that they wanted flexibility in court. They evolved a legal system seemingly inspired by relics of traditional Chinese attitudes as modified by their own guerrilla experience prior to 1949 and by study of Soviet practices during the period of War Communism before 1921.

Concurrently with revival of concern for humanistic values, Communist states other than China revised their constitutions and law codes to give formal support to their claim to have passed beyond capitalism to Socialism. Mongolia and Czechoslovakia declared themselves Socialist republics in constitutions adopted July 6 and 11, 1960, respectively. North Vietnam introduced its new constitution on Dec. 31, 1959. Yugoslavia promulgated its revision on April 7, 1963. New civil codes designed for Socialist economies were introduced in Poland and Czechoslovakia in 1964, the latter incorporating new terminology departing sharply from Romanist tradition.

Several features, however, remained unchanged in the law of these states even after the introduction of variations. Most notable was continuation of Lenin's principle that no basis remained after the Russian Revolution for the Romanist division of law into public and private spheres. To Lenin the Soviet state's concern with every detail of social intercourse required maintenance of the state's right and opportunity of intervention in any matter at any time. Consequently he held that in the Soviet system all law must be public, that is, reflect the state's vital concern in the social relationships governed by law. This attitude of state direction of all matters, sometimes called *dirigisme* by French scholars, remained characteristic of Soviet law.

The industrialization characteristic of the 20th century required legal systems in all states to accept increasing state intervention in social relationships. Employers were no longer left free to execute labour contracts as they wished; property owners were subjected to increasing restraints on use, and in some countries were subjected even to the loss of farms or dwellings if these were not used productively; nationalization in banking, industry, and transport was widespread; compulsory insurance against injury to third parties became commonplace, as did social insurance against industrial accidents; and secularization of marriage and divorce nearly everywhere prevented citizens from conducting their marital relationships solely within religious rules.

Soviet law, in its reflection of the state's pervading presence in human relationships, appeared to be but an extreme extension of trends common to legal systems everywhere. Yet many legal philosophers concluded that Soviet law differed in more than degree from other systems. While its techniques were those of the Romanist system, its difference in degree was interpreted as a dif-

ference in quality, justifying the conclusion that Soviet law was a unique system requiring separate categorization. *See* also UNION OF SOVIET SOCIALIST REPUBLICS: *The Judicial System.*

SOVIET UNION: *see* UNION OF SOVIET SOCIALIST REPUBLICS.

SOWER, CHRISTOPHER (1695–1758), printer and pietist leader of the Pennsylvania Germans, was born in Ladenburg, near Heidelberg, Ger., and lived for a number of years in Laasphe, duchy of Wittgenstein. He migrated with his wife and son Christopher (1721–84) to Germantown, Pa., in 1724, residing there until his death, except for a period of farming in Lancaster County, 1726–30. An artisan skilled in many crafts, and profoundly religious, he found his true career in 1738 as the first successful printer to the numerous Germans in colonial America. He imported press and type from Germany, but made his own ink and, occasionally, his own paper. The output from his large and prolific press included a newspaper, *Der Hoch-Deutsch Pensylvanische Geschicht-Schreiber,* retitled *Pensylvanische Berichte* in 1748, an almanac, *Der Hoch-Deutsch Americanische Calender,* and more than 150 other imprints, mostly religious and in German, ranging from broadsides to the first European-language colonial Bible (1743).

Though a separatist, he was sympathetic in Pennsylvania to the Church of the Brethren, founded in Laasphe while he lived there. His pietism was evident in all his activities. He urged the politically apathetic Pennsylvania-Germans to go to the polls to maintain pacifist and oath-denying Quakers in power. He worked for Christlike relations with the Indians, legislation to stop mistreatment of immigrants, dissemination of medical knowledge, building of hospitals, and maintenance of the German culture. He opposed defense measures, compulsory Anglicization of Germans, slavery, higher education, and traditional religions, with their forms, sectarianism, and professional clergy. He deeply appreciated the freedom and opportunities he found in Pennsylvania, despite the enmity of men such as Benjamin Franklin, who had fundamentally different principles and resented his great power among the Germans. Both his press and his principles were continued by his son Christopher after his death in 1758.

See F. Reichmann, *Christopher Sower, Sr., 1694–1758, Printer in Germantown; an Annotated Bibliography* (1943); E. W. Hocker, *The Sower Printing House of Colonial Times* (1948). (W. R. SL.)

SOWERBY, LEO (1895–), U.S. composer, teacher, and organist, was born at Grand Rapids, Mich., May 1, 1895. He studied in Chicago, where in 1917 he presented a program of his orchestral works and songs and in 1921 was named the first recipient of the American Grand Prix de Rome. He taught composition and theory at the American Conservatory of Music in Chicago from 1925 to 1962 and was organist at St. James's Church (now the Cathedral of St. James) there from 1927 to 1962. In 1962 he was appointed director of the College of Church Music in Washington, D.C.

Sowerby's early works were influenced by Max Reger and Grieg. His piano pieces, *The Irish Washerwoman* and *Money Musk,* later orchestrated, are in the manner of Percy Grainger. In *Synconata* (1924) and *Monotony* (1925) he experimented with jazz. His numerous vocal works include cantatas, services, anthems, and *Canticle of the Sun* (performed 1945), which won a Pulitzer Prize. His orchestral works include four symphonies. Besides concertos for piano, cello, and organ, Sowerby wrote many chamber works, including sonatas for wind instruments and piano.

See B. C. Tuthill, "Leo Sowerby," *The Musical Quarterly* (April, 1938). (N. SY.)

SOWING: *see* PLANTING MACHINERY.

SOYBEAN, also known in some countries as the soja bean and the soya bean, is an annual, summer leguminous plant (*Glycine soja* or *Glycine max*) native to eastern Asia and extensively cultivated in the United States. Cultivated in China and Japan long before written history, it is from the standpoint of uses and value the most important legume grown in those countries. Many records of soybean culture in China, some going back as far as 2207 B.C., give advice on soil preference, time of planting, varieties for different purposes and numerous uses indicating that the soybean was among the early crops grown by man. The crop was considered the most important cultivated legume and one of the five sacred grains (rice, soybeans, wheat, barley and millet) essential to the existence of Chinese civilization. In a Chinese dictionary dating from about the beginning of the Christian era the soybean is called *sou,* which very probably was the source of the names soi, soy, soya and soja.

Europeans first knew of the soybean through Engelbert Kaempfer, a German botanist who spent three years (1690 to 1693) in Japan. Kaempfer gave the Japanese name *daidsu mame,* and described it as an erect bean with the pod of a lupine and the seeds of a large pea. Although he discussed the many food products prepared from the soybean by the Japanese, little interest was taken in the crop.

In 1875 a great impetus was given to soybean culture in Europe through the experiments of Friedrich Haberlandt of Austria who grew the seed of several varieties obtained at the Vienna exposition in 1873. Seeds of the four varieties that matured were distributed widely in Austria-Hungary and other countries of Europe and gave promising results. Haberlandt published the results of his investigations in 1878, stimulating further research on the crop. While records show packets of seed being received in France as early as 1739 from missionaries in China, no record of successful culture of the soybean was established in that country until 1879, when a Chinese variety matured satisfactorily at Marseilles. In 1880 Vilmorin-Andrieux and Company introduced into France one of the yellow-seeded varieties tested by Haberlandt, which proved to be well adapted to French conditions. Soybeans were grown as early as 1790 in the Royal Botanic Gardens, Kew, Eng., but the crop is not well adapted to the English climate and there was no commercial production. Cultivation of the soybean in Italy dates from about 1840 but it has not become an important crop in any part of the country.

J. HORACE MCFARLAND COMPANY

PODS AND LEAVES OF THE SOYBEAN

The first mention of the soybean in the United States was by James Mease in 1804, who noted that it did well in the climate of Pennsylvania and recommended that it be cultivated. The Perry expedition to Japan in 1854 brought back two varieties of "soja bean"; for several years after that, the soybean was referred to as the Japan pea. In 1882, the North Carolina agricultural experiment station grew a yellow-seeded soybean, probably the Mammoth Yellow, which remained a leading variety in that area for many years. In 1889 W. P. Brooks of the Massachusetts agricultural experiment sta-

tion brought with him from Japan a number of varieties. The next year C. C. Georgeson secured three lots of soybeans from Japan and grew them at the Kansas agricultural experiment station. Since then most of the agricultural experiment stations in the United States have conducted extensive tests with the soybean crop.

In 1898 the U.S. department of agriculture began introducing large numbers of soybean varieties, mostly from Asian countries with a few from Europe and other parts of the world, and since then has grown and evaluated about 10,000 varieties of foreign origin. Probably among the first varieties secured from Europe were some used by Haberlandt in his early trials in Austria. Beginning in 1936 the U.S. department of agriculture cooperated with the agricultural experiment stations of states and Canadian provinces in developing improved soybean varieties through hybridization and selection. These improved varieties have higher yield and oil content and growth habits more suitable to modern farming methods than the Asian varieties. Increase of acreage and production has been closely correlated with the introduction of these varieties and their improvement through breeding and selection. The improved varieties developed through cooperative research have also contributed very substantially to the increased industrial value of the crop.

Areas of Production.—*Asia and Australia.*—The soybean is grown intensively in China including Manchuria. It is the cash crop of the Manchurian farmer and occupies about 25% of the total cultivated area of that region. In the second half of the 20th century China (with Manchuria) was producing nearly 340,000,000 bu. a year or about 40% of the world total. Other important soybean-producing countries of Asia are Indonesia, Japan, Korea, Formosa (Taiwan), Thailand, and India. The soybean is cultivated in the Philippines and grown successfully in parts of Australia and New Zealand.

Europe and Africa.—The climate of Europe is not generally suited to soybean culture although there is limited production in Italy, Yugoslavia, Rumania, and southern U.S.S.R. There is some soybean culture in Africa, mainly in Tanzania, the Congo, Nigeria, and the Republic of South Africa.

North and South America.—In the Western hemisphere, the United States was the leading soybean-producing country, accounting for nearly 60% of world production. Approximately 83% of the U.S. soybean production is in the north central states. Other areas of heavy production are in the Arkansas and Mississippi delta area of the Mississippi River and along the middle Atlantic coast. Soybeans became a major crop in the United States, with production increasing from 5,000,000 bu. in the mid-1920s to more than 700,000,000 bu. in the 1960s. Another important soybean-producing area in North America was in the province of Ontario, Can. In South America, Brazil and Argentina were becoming important soybean-producing countries.

Plant Characteristics.—The soybean is an erect, branching plant, resembling in its early growth ordinary field and navy beans. Varieties range in maturity from early to late, and in height from less than one foot to five or six feet. The root system constitutes about 10% of the weight of the plant but is well branched and often extends to a depth of four or five feet. The characteristic deep roots are responsible in part for the great resistance to drought offered by soybeans. Except for the pair of simple leaves on the first node above the cotyledons, the leaves are trifoliate and borne one to a node. They vary widely in shape, size, colour, and degree of persistence (leaf remaining attached to the stem), though they usually turn yellow as the pods ripen and are shed by the time the plant is ready to harvest. Nearly all varieties are pubescent; *i.e.*, the stems, leaves and pods are covered with fine tawny (brown) or gray hairs.

Several yellow-seeded varieties in the orient are entirely glabrous, that is, lack pubescence; these usually are smaller, shorter, and yield less seed than most pubescent varieties, and when grown in North America are subject to considerable injury from leafhoppers. In the orient, the glabrous varieties have been found highly resistant to attacks by the pod borer, a serious insect pest, which as yet has not been found in North America.

In the axil of each leaf is a bud that may develop into a branch or flower. The flowers are small and inconspicuous and are either white or different shades of purple. They contain both male and female parts and are almost completely self-fertilized although in the field there is usually around 1% cross-fertilization.

The pods, usually containing two or three seeds, range in colour from light straw or tan through shades of gray and brown to nearly black. Those of the wild soybean and a few hay-type varieties dehisce (open and scatter their seed) readily as the seed matures, although most commercial varieties have been selected for the ability to hold their seed for two or more weeks after maturity.

The seeds are usually yellow, green, brown or black but may be bicoloured. No truly white or red seeds are known in soybeans. The most common bicoloured patterns are green or yellow with a saddlelike patch of black or brown extending down on each side of the hilum or seed scar. Some seeds are brown and black with the patterns concentrically arranged. The cotyledons of soybeans may be yellow or green. Varieties with yellow seed coats and yellow cotyledons are preferred for industrial processing. Seed size varies greatly from the 30,000 seeds per pound of the wild bean to 1,200 seeds per pound for some vegetable varieties. Most commercial varieties range in seed size from 2,500 to 3,500 seeds per pound.

Cultivation.—The soybean will succeed on nearly all types of soils but does best on fertile or sandy loams. In general, soil requirements are about the same as those for corn or cotton. Like other legumes, soybeans obtain part of their nitrogen requirement from the air through the action of certain nodule-forming bacteria living on the roots of the plant. Where soybeans have not been grown previously it is advisable to inoculate the seed with the soybean bacteria just before sowing. (*See* NITROGEN, FIXATION OF.) In the United States soybeans are usually planted during May or early June in rows 30 to 40 in. apart. Early cultivations to kill small weeds or to break a soil crust are usually done with a rotary hoe or harrow starting soon after the plants emerge. Later cultivations are done with regular row equipment used for corn or cotton. Chemical weed control is dependent to some extent on weather conditions.

Approximately 50 diseases are known to attack soybeans, but only a few have caused serious economic losses. Varieties resistant to leaf diseases have been developed, and diseases can be controlled to some extent by planting resistant varieties and following proper cultural practices. Several insects attack soybeans and cause severe losses, but good control may be obtained by timely dusting or spraying with a number of different insecticides. (*See* SPRAYS AND DUSTS IN AGRICULTURE.)

When soybean varieties are grown in their area of best adaptation they mature during September or October, utilizing the full growing season. Flowering and ripening in soybeans are controlled by length of day and night (photoperiod) in which the plants are growing. Soybeans are called short-day plants because under normal conditions they will not start blooming or maturing until the day length is shorter than a certain minimum value which is specific for each variety. This is the reason that a soybean variety is adapted to a rather narrow belt of latitude; and why, for example, in the northern hemisphere, if a variety is planted north of its proper latitude, blooming and ripening will be delayed in the longer summer days and the plant may be caught by frost. Conversely if a variety adapted in the north is moved to a lower latitude it will bloom and mature too early and will not take advantage of the full growing season.

Most soybeans are harvested by a combine, which threshes as it reaps, when the plants are mature, the leaves have fallen and the seed has dried to a moisture content of about 13%, at which time the crop can be stored safely.

Uses.—*Food and Food Products.*—In Asian countries the soybean is grown primarily for the seed, which is used largely in the preparation of hundreds of fresh, fermented, and dried food products. These various food preparations not only give flavour to the oriental diet but supply to a considerable extent the necessary protein in the diet. This has been especially true inland, where seafood is not readily obtainable. Nutritionally the protein of the soybean is similar to that of animal protein—even the amino acid analyses of soybean protein and casein are remarkably similar.

Sprouts grown from soybean seed are eaten by the Chinese as a green vegetable throughout the year, either in salads or as a cooked vegetable. They are a good source of vitamin C. Soybean "milk" (soybean flour suspended in water) is said to have been made long before the Christian era. It is used in the fresh state and also in the manufacture of bean curd or vegetable cheese *teou fu* or *tōfu* used so extensively in the orient. When soybean milk is boiled a film called *yuba* forms on the surface. This film is rich in protein and has been a popular food in China and Japan since ancient times. In cooking, *yuba* is either fried or used in soups. *Nattō* and *miso*, prepared by steaming and fermenting soybeans, are two staple foods in Japan. Red *miso* contains a large amount of salt and will keep for several years.

Soy sauce (*shōyū*), a fermented product made from soybeans and parched wheat, is a very salty dark-brown liquid used extensively both in the orient and the west as a seasoning. In China and Japan soybeans are boiled in syrup and eaten as candied beans and also soaked in salt water and roasted as a nut.

In the U.S. soybeans are used as a green vegetable and are preserved by canning or freezing. The mature or dry soybeans are baked or boiled in a manner similar to navy beans. For this purpose special vegetable varieties have been developed that are bland or nutty in flavour.

The soybean was first used in the U.S. as a forage crop and for green manure. When properly harvested and cured the soybean plant makes excellent hay. Soybeans are especially valuable for plowing under before planting certain crops such as sugar cane. The first commercial processing of soybean seed to obtain oil and cake was in 1911 when a small hydraulic-press mill in Seattle, Wash., processed a shipment of beans from Manchuria. In 1915 a cotton-oil mill in Elizabeth City, N.C., using screw-press equipment, made a successful start in processing locally grown beans. In 1917 a plant in Chicago Heights, Ill., began crushing experiments using both hydraulic and screw-press equipment, although the supply of soybeans was not adequate at that time to keep the mill in operation. A corn-processing company in Decatur, Ill., began crushing soybeans in 1922. Several other processing companies built soybean mills in Decatur in the late 1920s and 1930s, and the city soon became recognized as the leading soybean-processing centre in the U.S. It was not until 1935 that the acreage of beans for processing equaled that for forage but thereafter the volume of processing increased very rapidly.

Processing of the beans for oil and meal by hydraulic pressing or by expeller or continuous pressing (screw presses) left from 4 to 5% oil in the press cake. Most processing plants in the U.S. and Europe changed to hydrocarbon solvent extraction, which leaves around 1% oil in the meal. With modern extraction equipment a bushel (60 lb.) of soybeans produces about 11 lb. of crude oil and 47 lb. of meal.

Soybean oil contains from 80 to 85% unsaturated glycerides and is classed as a semidrying oil. With an iodine number (an index of drying rate) of 130 to 135 it lies between rapid-drying oils such as linseed and tung, and the nondrying oils such as peanut oil. Methods of refining have been developed that make soybean oil very good for edible products such as shortening, margarine and salad oils. The generally low fatty-acid content of soybean oil results in a low refining loss and high yield of refined oil. Cooking oils and salad oils may be prepared by refining, deodorizing, and bleaching soybean oil. By controlled hydrogenation that partly solidifies the oil, an excellent solid fat can be prepared for use in the manufacture of shortening and margarine. (*See* OILS, FATS AND WAXES.)

Crude soybean oil contains from 1 to 3% lecithin—an antioxidant, emulsifier, and softener used in food manufacturing and many other industries.

Soybean meal remaining after the oil has been extracted is a valuable product with many uses, particularly as a high-protein feed for livestock and poultry. In the second half of the 20th century about 95% of the soybean meal consumed in the U.S. was used for feed, supplying over 6,000,000 tons or 66% of the total vegetable protein meal consumed by livestock and poultry (*see* ENSILAGE; FEEDS, ANIMAL). Soybean flour, grits and flakes are used in bread, doughnuts, cakes and cookies; as emulsifiers and binders in sausages and related meat products; in breakfast foods, salad dressings, low-starch health foods, macaroni and noodles, confectionery products, ice creams and as whip toppings. Soybean flour proved very successful in meeting food shortages during emergencies. Cereal proteins are low in lysine content, and soybean protein supplies the deficiency. The addition of 5% soybean protein to wheat flour makes a remarkable improvement in nutritive value. It has been stated that soybean flour is one of the cheapest foods available to man when judged by the amount of protein, minerals, vitamins and energy obtainable per unit of cost. Soybean meal also is used in the brewing industry to provide nutrients for the growing yeast and to improve the flavour and body of beer. While whole soybeans are generally used in the preparation of soy sauce by fermentation, soybean meal is used by many manufacturers in its preparation by the more rapid acid hydrolysis method. Monosodium glutamate, an important condiment in the orient and in the U.S., may be prepared by acid hydrolysis of soybean meal. Glutamic acid is an essential constituent of soy sauce.

Uses in Industry.—Although food manufacture absorbs about 85% of the soybean oil consumed in the U.S., the oil has many applications in industry, one being in the production of high-grade industrial enamels, particularly white enamels for kitchen appliances and coloured enamels for automobile finishes. It is used extensively in the production of varnishes and alkyd resin paints and also is used in inks and stains, sealing and caulking compounds, linoleum and oilcloth, pharmaceuticals, cosmetics, synthetic rubber and core oils. The protein in soybean meal is readily soluble in water and when properly processed is similar to casein in viscosity, adhesive strength and many other characteristics. Soybean protein is used in many industrial applications such as adhesives, paper coatings, water-thinned paints, plastics, textile fibres, fire foam stabilizers, printing inks, fillers, core binders, stickers for agricultural sprays, linoleum, emulsifying agents, paper and textile sizing and leather finishes. In the plywood industry soybean glues represent the largest tonnage of any type of adhesive used. Industrial research is rapidly widening the industrial uses of the soybean and its products.

SOZOMEN (SALAMANES HERMEIAS SOZOMENOS) (fl. *c.* A.D. 425), church historian whose work supplements that of his contemporary Socrates, was born of a Christian family at Bethelia near Gaza and was brought up in Palestine, of which he shows considerable knowledge. Later, not before 425, he worked as a lawyer in Constantinople. He compiled a history of the church running parallel to that of Socrates (*q.v.*) and generally similar to it; in fact, it is largely based upon Socrates' work, though without acknowledgment, and presumably was written in a competitive spirit. In nine books, it is dedicated to the emperor Theodosius II, was begun in the 440s, and was intended to cover A.D. 324 to 439 but stops in 422 with occasional references to later events. It has been variously suggested that Sozomen died before completing it, that the conclusion has been lost, or that either he or the emperor suppressed the conclusion to avoid reference to the empress Eudocia, who had fallen from favour.

Sozomen normally follows Socrates closely, but he frequently consulted the documents used by Socrates and sometimes cites them more fully. He also drew upon additional sources, such as further works of Athanasius and, for the political detail of book ix, the collections of his contemporary the pagan historian Olympiodorus of Thebes. He is more favourable to monks (by whom he was perhaps educated) and gives more of their history, and he sides definitely with Chrysostom. Though Sozomen was somewhat less critical than Socrates, his history is a valuable supplement to, and sometimes corrects, the earlier one and, like it, was used by Theodore the Lector for his *Tripartite History* (early 6th cen-

tury). His style is better than that of Socrates, who was reacting sharply from the verbosity and artifice of their historian-predecessor Eusebius of Caesarea.

SPA, a town in the province of Liège, Belg., 21 mi. (34 km.) SE of Liège, famous for its springs of mineral water, known locally as *pouhons*, which have caused the name spa to be given to all such health resorts. The springs are said to be beneficial to sufferers from heart diseases. Pop. (1961) 9,055. The town became fashionable in the 18th century, when the coloured wood carvings (*bois de Spa*) were also popular. In 1807 much of the town was burned down, and the principal buildings, the casino and the baths, are modern. The surrounding Ardennes scenery is picturesque. In 1918 the emperor William II made his headquarters at Spa, and in 1920 the conference to discuss the terms of the Treaty of Versailles was held there (*see* SPA, CONFERENCE OF).

SPA, CONFERENCE OF, an important meeting of the Supreme Council of the Allied Powers in the aftermath of World War I. It took place at Spa, in Belgium, from July 5 to July 16, 1920. The problems of German disarmament and reparations and the Polish demand for Allied assistance against Soviet Russia were the main items on its agenda. Great Britain was represented by David Lloyd George (prime minister) and Lord Curzon (foreign secretary); France by Alexandre Millerand (prime minister); Italy by Count Carlo Sforza (foreign minister). They were joined by Léon Delacroix, the Belgian prime minister. Moreover, for the first time since the signature of the Treaty of Versailles, a German delegation was invited to present its views. This delegation comprised Konstantin Fehrenbach (chancellor of the *Reich*), Otto Karl Gessler (defense minister), Gen. Hans von Seeckt (commander of the *Reichswehr*), and others.

The Germans made a formal request that the figure of 100,000 men, which was the limit of the German Army allowed by the Treaty of Versailles, might continue to be exceeded, on the ground that it was impossible for the government to keep order with such a small force. Lloyd George explained the Allies' anxiety over the fact that Germany still had an army of 200,000 men, with 50,000 machine guns and 12,000 guns. It was decided that Germany should reduce the strength of the *Reichswehr* to the treaty figure of 100,000 by Jan. 1, 1921, and withdraw arms from semimilitary formations. On July 9 the Germans signed an agreement embodying these stipulations.

The problem of the reparations (*q.v.*) due from Germany under the treaty remained unsolved, but on July 16 Germany agreed to deliver 2,000,000 tons of coal monthly to France, Italy, and Belgium by way of reparation. The Allies agreed among themselves as to the distribution of the still uncertain total of German reparations: France was to receive 52%, the British Empire 22%, Italy 10%, Belgium 8%, and Serbia 5%.

The question of "war criminals" was allowed to lapse by the conference. As the Netherlands government had on Jan. 23 refused to deliver the ex-emperor William II to the Allies, they decided not to ask the German government to hand other accused persons over to them. Instead, they asked the Germans themselves to proceed with trials and punishment; but the German government was unwilling to do so.

Since the Russo-Polish War (*q.v.*) was going badly for Poland, Wladyslaw Grabski, the Polish prime minister, went to Spa on July 6, 1920, to appeal urgently for moral and material assistance. The Allies decided to intervene diplomatically in Moscow, the British government taking the initiative. Lloyd George promised to send a note to the Soviet government requesting an armistice along a line described later as the Curzon Line (*see* POLAND: *History; Independence Restored*); but at the same time he pressed Poland (1) to renounce Lwow (Lvov) and the whole of eastern Galicia, (2) to leave Wilno (Vilnius) to Lithuania, (3) to agree to a partition of Teschen Silesia by the Allies without plebiscite, and (4) to accept, in the Free City of Danzig, a Harbour and Waterways Board, which had not been stipulated by the Treaty of Versailles. On July 10 Grabski signed an agreement embodying these conditions; and on July 11 Curzon started a telegraphic correspondence with G. V. Chicherin, the Soviet people's commissar for foreign affairs. Grabski left Spa convinced that at least arms and munitions in considerable numbers would be sent to Poland, but in fact no such help arrived before the Poles themselves had won their victory. (K. SM.)

SPAAK, PAUL HENRI (1899–), the foremost Belgian statesman of the decades following World War II, a champion of the North Atlantic Treaty Organization (NATO) and of European cooperation. He was born at Schaerbeek (Greater Brussels) on Jan. 25, 1899, the son of the poet and dramatist Paul Spaak and his wife Marie (née Jeanson). In 1915, during World War I, he tried to join the Belgian Army on the Yser River but was arrested by the Germans. Released at the end of the war, he studied law in Brussels and was called to the bar there.

Elected to the Chamber of Deputies as a Socialist in 1932, Spaak became minister of transport, posts, and telegraphs (March 1935–May 1936) and then foreign minister (June 1936–May 1938) in Paul van Zeeland's cabinets. As foreign minister he conducted the negotiations to release Belgium from the Pact of Locarno (*q.v.*), believing that Belgium could remain neutral in the event of war between Germany and the Western Powers. He became Belgium's first Socialist prime minister in May 1938 but resigned in February 1939. Foreign minister again from September 1939, in Hubert Pierlot's coalition, he went into exile with the government in May 1940 after the Belgian Army's capitulation to the Germans during World War II. In London, he laid the foundations of Benelux (*q.v.*) in September 1944. He returned to Brussels that same month and remained foreign minister in the coalition governments of 1945–47 under Achille Van Acker and Camille Huysmans. On Jan. 10, 1946, Spaak was elected president of the first session of the General Assembly of the United Nations.

From March 1947 to August 1949, Spaak was prime minister, with a Christian Social-Socialist coalition: he brought Benelux into operation (1948) and signed the North Atlantic Treaty (1949). In the summer of 1950 he took an active part in the political outcry that led to the abdication of King Leopold III a year later.

Spaak was elected president of the Council of Europe's Consultative Assembly in May 1951 and president of the European Coal and Steel Community's General Assembly in September 1952. He was Belgian foreign minister again in Van Acker's Socialist-Liberal coalition from April 1954 to May 1957, when he resigned in order to work as chairman of the Atlantic Council and secretary-general of NATO. He returned to Belgian politics, as leader of the Socialist Party, in 1961 and became deputy prime minister and foreign minister in a Christian Social-Socialist coalition. He opposed the transformation of the European Economic Community into a political one before the admission of Great Britain to it.

SPAATZ, CARL (1891–), U.S. Air Force officer, the leading U.S. combat air commander of World War II and first chief of staff of the independent United States Air Force, was born at Boyertown, Pa., on June 28, 1891. After a distinguished career as a combat pilot during World War I, Spaatz acquired extensive staff and command experience between 1919 and 1942. As commander of the 8th Air Force in England during World War II, he initiated the American daylight bombing offensive against Germany in 1942. In January 1944 he became commander of the U.S. Strategic Air Forces in Europe and directed the daylight strategic bombing of Germany from both England and Italy until the end of the war in Europe. He moved to the Pacific in July 1945 in time to direct the final strategic bombing of Japan, which culminated in the dropping of atomic bombs on Hiroshima and Nagasaki. Spaatz became chief of staff of the newly independent Air Force in September 1947, but, finding the administrative burden not to his liking, he retired in 1948. (A. GG.)

SPACE EXPLORATION. Space is not empty—not even those regions that lie between the stars and the planets. Throughout the vast reaches of space, matter (largely hydrogen) is scattered at the extremely low density of perhaps one atom per cubic centimetre in interstellar space and about ten particles per cubic

TABLE I.—*Regions of Space: Earth's Atmosphere and Near Space*

Distance from Earth's centre (Earth radii)	Altitude (km.)	Environmental characteristics						Operational aspects	
		Dynamic	Chemical	Electrical	Thermal	Meteors	Gravitational	Technical	Medical
1–1.0024	0–15	Winds Turbulence	20.9% O_2, 78% N_2 0.9% Ar, 0.03% CO_2, variable amount H_2O (volume %)	Thunderstorms	Average temperature gradient about −6.5° C./km.	Very rare	Terrestrial	Air-breathing engines	Ceiling for use of an oxygen mask: 3 km.: O_2 required 7.5 km.: ceiling for operational crew (U.S. air force) 11 km.: ceiling for all personnel (U.S. navy) 12 km.: ceiling for passengers at rest (U.S. air force) 13 km.: ceiling for pressure breathing (U.S. navy)
1.0024–1.0048	15–30	Lower region: jet streams	Ozone appears; maximum concentration at about 25 km.	None	Approximately isothermal atmosphere about −50° C.	Very rare	Terrestrial	30 km. is limit for most air breathing engines; hypersonic ram jets may extend beyond Slow-down region of ICBM nose-[illegible]	10–25 km · pressurized cabin 25 km : sealed cabin; beginning of space equivalence
1.0048–1.0126	30–80	Turbulence in region of negative temperature gradient	Above 50 km., atomic oxygen appears	D layer (daytime) NO^+ predominant ion	30 to 50 km.: +2 to 3° C /km. 50 to 80 km.: −1.5 to −4° C./km. Temp. at 75 km.: −73° C.	Most meteors disappear Accumulation of meteoritic dust	Terrestrial	Slip-flow region Slow down region of entry gliders from space Radicals for propulsion	Space equivalence Aerodynamic heating Cosmic radiation (maximum atmospheric secondaries)
1.0126–1.063	80–400	Hydromagnetic effects on dynamics Pressure about 10^{-6} atmosphere at 100 km.	O_2 dissociated Slight N_2 dissociation Airglow processes Aurorae	E, F_1, F_2 layers O^+, NO^+, O_2^+ major ions present	Temperature increases rapidly with altitude 100 km.: −53° C. 150 km.: +672° C. 300 km.: +1,170° C.	Meteors visible below about 100 km.	Terrestrial Perturbation of satellite orbits due to Earth's oblateness	Free molecule flow region Lower satellite orbit region; departure orbit for lunar and interplanetary probes	Space equivalence
1.063–1.157	400–1,000	Pressure about 10^{-12} atmosphere at 500 km. Lower edge of magnetosphere over equator	Helium becomes significant	O^+ ion predominates He^+ present Lowest portion of Van Allen radiation belts	Temperature becomes isothermal with altitude, but is subject to large diurnal variations	Micrometeorites and meteorites	Same as above	Manned space stations Instrumented satellites	Space conditions Corpuscular radiation
1.157–1.5	1,000–3,200	Some particles escape from Earth's atmosphere Magnetosphere	Hydrogen is predominant	H^+ present Charged particles travel along magnetic force lines Van Allen radiation belts	Diurnal effects predominate	Micrometeorites and meteorites	Same as above	Instrumented satellites	Space conditions Increasingly intense corpuscular radiation

centimetre in interplanetary space. Space is permeated by gravitational fields, traversed by an extremely broad spectrum of electromagnetic radiation and by cosmic rays, and is occupied by magnetic fields of unknown intensities and distributions. Although the scientist has deduced much about space from observations made at the Earth's surface, only with the advent of the artificial satellite and the deep-space probe has he been able to discover at first hand the great complexity of space phenomena.

This article is concerned with the exploration of space by those methods made possible by the large modern rocket. For the purposes of this discussion, the term space should be regarded generally as meaning those reaches of the universe lying beyond the Earth's sensible atmosphere. This definition of space is imprecise, but efforts to sharpen it become extremely complicated. For the biologist outer space means one thing, for the legal expert another, and for the astronomer something still different. The lawyer, who is concerned with the question of where existing international agreements concerning aviation should be considered to apply and where new agreements concerning astronautics should be developed, has an extremely difficult task when he attempts to develop a precise definition of space. Many of the applications of space technology apply primarily to activities on the surface of the Earth—for example, in the making of weather observations, in communications and in navigation. Even in the area of scientific exploration it becomes impossible for the scientist to separate the study of near space from the science of the Earth's atmosphere and ionosphere, and satellite investigations of the Earth's gravitational field by means of artificial satellites lead to important results in geodesy and in the study of the internal structure of the Earth. Tables I and II list some of the properties and characteristics of various regions of space.

The rocket in one form or another furnishes the only practicable means for transportation through space. Late in the 19th century the Russian mathematician Konstantin Tsiolkovski called attention to the usefulness of rockets for this purpose. Robert Goddard, a U.S. physicist, was motivated in his pioneering work on rockets, during the 1920s and 1930s, by the desire to send research instruments into the Earth's upper atmosphere. A German group, led by Hermann Oberth in the 1920s, looked to interplanetary travel as one of its principal objectives.

As these early pioneers clearly foresaw, space activities did not, indeed could not, come into being until the rocket had been further developed. Although the beginning of the space age is associated with the launching of the first Soviet Sputnik on Oct. 4, 1957, the groundwork for this event was laid by the high-altitude rocket exploration of the preceding decade. Beginning in 1945 with the launching of a WAC Corporal rocket, the United States undertook a series of scientific experiments in the Earth's upper atmosphere. For some years captured German V-2 rockets furnished the principal means of carrying on this upper-air research. With the development of the Aerobee, Viking and other rockets more suited to upper-atmosphere exploration, the work with sounding rockets accelerated, reaching a peak of activity during the International Geophysical Year (1957–58). Upper-air re-

search in the Soviet Union followed a similar chronology.

In both the U.S. and the Soviet Union the development of missile technology was essential to the larger satellite and space probe applications. As preparations for the International Geophysical Year (IGY) progressed, the possibility of launching artificial Earth satellites for scientific investigations became more and more apparent. As a result, the planning committee for the IGY in 1954 passed a formal resolution calling attention to the desirability of using artificial satellites in the IGY program. Both the United States and the Soviet Union responded with announcements that they would prepare scientific satellites for launching during the IGY. The first Soviet Sputniks and the early Explorer and Vanguard satellites of the U.S. were the direct outcome.

Although the possibilities offered by artificial satellites had been apparent to scientists and engineers working in these fields, general recognition of their potentialities did not take place until the first satellite was in orbit. After the launching of the first satellites, the U.S. created the National Aeronautics and Space administration (NASA) by the Space act of 1958. Under this act NASA took over the personnel, facilities and aeronautical responsibilities of the former National Advisory Committee for Aeronautics and also assumed responsibility for the civilian space activities. NASA began functioning on Oct. 1, 1958.

Thereafter, U.S. space activities expanded tremendously. The space budget grew rapidly from its initial total of $331,000,000 in 1959 to about $5,000,000,000 by the mid-1960s. The program encompassed research efforts in aeronautics, space science, space applications, manned space flight and research on advanced technology. In addition, the U.S. department of defense developed a program for the application of space techniques to defense uses, and by the mid-1960s the budget for these purposes was about $1,600,000,000. Also, the Atomic Energy commission was cooperating with NASA in the development of nuclear techniques for space, while the department of commerce was playing an ever-increasing role in the use of satellites in meteorology and geodesy.

This article is divided into the following sections:

In reading these sections the following definitions and concepts will be useful. Rockets used to launch spacecraft into orbit are referred to as space vehicles or launch vehicles. Most of them are multi-stage vehicles. It is customary to refer to the first stage as the booster stage and to the remaining parts of the rocket as upper stages. The term spacecraft is used in a general sense to describe the assemblage and its payload that is lifted into space and injected into an orbit by a launch vehicle. If the launching rocket with its payload follows a vertical or nearly vertical trajectory, and remains within one Earth radius of the ground, then the combination is normally referred to as a sounding rocket. When the spacecraft is injected into a closed orbit about the Earth, it becomes an artificial satellite of the Earth. The orbit is described by four factors: apogee and perigee, the points farthest from and nearest to Earth, given in miles or kilometres; the inclination of the plane of the orbit to the plane of the Earth's equator, given in degrees; and the period, or time required for one circuit of the orbit. Spacecraft that are injected into trajectories leading to escape from the Earth are called space probes. These may be classified as lunar, Venus, Mars, deep-space, etc.

The sounding rocket, artificial satellite and deep-space probe provide the scientist with a powerful means for research in a number of areas. Among the important subjects of investigation by space techniques are: the space environment; Sun-Earth relations; investigation of the Moon; investigation of the planets; determination of astronomical constants; investigation into the nature of the universe; and life in space.

Each of these areas can be investigated along lines that were impossible prior to the advent of the rocket. Of particular importance is the opportunity in astronomy to observe celestial objects and phenomena in the gamma ray, X-ray, ultraviolet, infrared and radio wavelengths that cannot penetrate the Earth's atmosphere to reach observatories on the ground. Especially exciting is the possibility that space biology may contribute significantly to efforts to develop a comprehensive biological theory. This collection of researches carried out in space or by means of space techniques is referred to as space science.

The scientific applications and technological advances made during the first five years of the space age were truly remarkable, but perhaps the most important aspect of this early phase of the space age was the establishment of a new capability in human endeavour. Out of these early activities man could develop the knowledge and techniques; trained and experienced personnel; assembly, launch, tracking and telemetering facilities; industrial complexes and teams; flight "hardware," and the ability to operate in space that go to make up a total space capability. With this capability, man can extend his domain beyond the earth as he once did over the land and the seas, into the air and into the ocean depths. (H. E. NL.)

I. ASTRODYNAMICS

Astrodynamics is the branch of astronautics that deals with the mathematical theory of the motions of spacecraft. These motions may be separated into two groups: the translations of the centre of mass of the spacecraft, and the rotations of the spacecraft about its centre of mass. The translations describe the flight path or trajectory or orbit of the spacecraft; the rotations describe its wobbling or angular motion.

In each of the two groups there are three motions. The translational motions are (1) surge, a motion generally along the velocity vector or direction of travel of the spacecraft; (2) heave, a motion perpendicular to the surge and generally in the direction of the gravity vector; and (3) swerve, a motion perpendicular to the surge and the heave. The rotational motions are (1) roll, a spinning motion around the velocity vector of the spacecraft, *i.e.*, spin about the surge direction; (2) pitch, an angular motion about the swerve direction; and (3) yaw, an angular motion about the heave direction. Thus, a spacecraft has a total of six motions which must be completely accounted for if its performance is to be known accurately, or if its position and attitude in space are critical to accomplishing its basic mission.

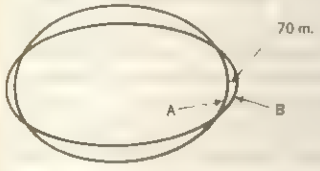

FIG. 1.—EQUATORIAL BULGE IS 21.4 KM. DISCREPANCY BETWEEN OBSERVED SHAPE (A) AND SHAPE OF HYDROSTATIC EQUILIBRIUM (B) IS 70 M.

The theory and applied mathematical methods of astrodynamics depend heavily on the methods of celestial mechanics, exterior ballistics and the flight dynamics of aircraft and missiles.

A. Two-Body Motion

Sir Isaac Newton stated that a sphere, such as the Earth, which is homogeneous in concentric layers, attracts an exterior point mass, such as a spacecraft, as if all of the mass of the sphere were concentrated at its centre. Furthermore, his universal law of gravitation states that any two particles of mass in the universe attract each other with a force that varies directly as the product of their masses and inversely as the square of the distance between them. Thus, a statement of a problem concerning the translational motions of a spacecraft takes the form of a set of equations of motion, which are ordinary differential equations of the second order. A proper understanding of astrodynamics, therefore, requires a knowledge of this branch of mathematics.

For the case of two bodies, such as a spacecraft and a simple spherical Earth, a solution to the differential equations of motion is known. Two types of translational motion are possible. The first is an elliptical or circular orbit of the spacecraft around the Earth. The second is a flight path away from the Earth, a path that may be hyperbolic or parabolic in shape.

While these simple solutions are quite useful in many cases, they are not correct, strictly speaking, since the Earth is not a simple spherical body. It is known, for example, that the Earth has a bulge at its equator. (*See* fig. 1.) This bulge, although amounting to only 21.4 km., seriously affects the motion of a spacecraft. For example, a spacecraft in a nominally circular polar orbit experiences a greater attraction as it passes over the equator and thus it is pulled toward the Earth. Also, its velocity is increased. When the spacecraft passes over the poles, it feels a lesser attraction and therefore it moves out farther from the Earth and its velocity decreases. The bulge at the equator, therefore, has caused a surging and heaving motion of the spacecraft as well as a variation in its altitude. Also, for a spacecraft in a 500-mi. orbit, the perigee altitude variation is approximately 5 mi. in two months.

For a spacecraft in an inclined orbit the bulge also causes the major axis of the orbit to rotate in the orbital plane and the orbital plane to rotate in space about the Earth's spin axis. The size of these two rotations depends upon the exact inclination of the orbital plane to the equator of the Earth. At an inclination of 63.4° there is no rotation of the major axis. For angles less than 63.4° the major axis rotates in the same direction as the satellite motion around the earth. For angles greater than 63.4° the major axis rotates in the opposite sense. There is no rotation

TABLE II.—*Regions of Space: Orbital Space*

Region	Distance*	Environmental conditions	Astronautic aspects
Terrestrial space (Ehricke) Magnetosphere	1–10 r⊕	Atmospheric effects on orbit in inner terrestrial space. Electrical and magnetic effects caused by Earth; especially the high-intensity radiation belt with maximum at 1.5 and 3.5 r⊕, outer limit 10–15 r⊕ on sun side Gravitational dominance of terrestrial perturbations over lunar perturbations	Manned space stations appear safe in region between relevant atmosphere (450 km.) and beginning of intense corpuscular radiation (650 km.); or beyond radiation belt (>15 r⊕) Instrumented satellites: meteorological: 1.1–6.5 r⊕ observational: 3-6.5 r⊕ (6.5 r⊕ = 24 hr. orbit) communication: 3-6.5 r⊕
Cislunar space (Ehricke) Magnetosphere (on antisolar side of Earth)	10–50 r⊕	Equivalence and finally dominance of lunar perturbations over terrestrial perturbations. Gravitational pull of Moon alternately joins and opposes Earth's pull Solar perturbation may be effective on cislunar transfer orbits Tail of Earth's magnetosphere on antisolar side	Essentially research satellites to explore environmental conditions in cislunar space Region is traversed by lunar and interplanetary vehicles Region of chemical and nuclear heat-exchanger rocket drives
Translunar space (Ehricke)	70 to ~300 r⊕	Outer region of geocentric space Lunar and terrestrial gravitational forces never act in opposite direction	No firm technical concepts yet on utilization of translunar space
Region in which the Moon can hold a satellite	40–45 r☾	Lunar gravity field dominant Special environmental conditions near the Moon, not yet known in detail	Lunar satellites Lunar base
Inner solar system	0–1.6 A.U.†	Central force field of the Sun Intense radiation Zodiacal dust cloud	Region of nuclear heat-exchanger drives for fast missions, low-thrust drives for large payload missions
Ecosphere (Strughold)	~0.5–1.5 A.U.†	Liquid water belt Oxygen belt Biotemperature belt	Natural biotechnical region of solar system
Outer solar system	1.6–38 A.U.†	Central force field of the Sun Strong perturbation potential of major planets	Low-thrust drives (electrostatic or electrodynamic)
Region in which respective planet can hold a satellite	Generally greater than 150 planet radii (except Mercury)	Gravitationally, a local anomaly in heliocentric space Probably special electrical, magnetic and radiation conditions not yet known in detail	Region in which artificial satellites can be established
Region in which the planet rather than the Sun should be considered as centre body for an arriving or departing body	Venus: ~100 r♀ Earth: ~144 r⊕ Moon: ~34 r☾ Mars: 170 r♂ Jupiter: 690 r♃	Gravitationally defined as the region in which the Sun is a lesser perturbative force in the planetocentric co-ordinate system than the planet is in the heliocentric co-ordinate system. A co-ordinate system is the frame of reference in which the orbit of the spacecraft (or comet, etc.) is measured. Its centre is in the centre of the planet or the Sun, respectively, for the two above mentioned co-ordinate systems	Region in which transfer from heliocentric to planetocentric orbits (capture) or the reverse (escape) takes place. The transfer orbit between a closed planetocentric (satellite) orbit and a heliocentric (elliptic) orbit is a hyperbola. The limit of the activity sphere is reached when the hyperbolic orbit merges with the heliocentric orbit

*r⊕ = Earth radius; r☾ = Moon radius; r♀ = Venus radius; r♂ = Mars radius; r♃ = Jupiter radius; each measured from the centre of the respective planet.
†1 A.U. = 1 astronomical unit = mean distance from sun to earth, measured from the centre of the sun.

or precession of the orbital plane when the inclination is 90° (polar orbit). Maximum precession, however, occurs for an equatorial orbit.

1. Effect of Asymmetrical Bodies.—Previous work in celestial mechanics on the motion of the innermost satellite of Jupiter and the innermost satellite of Saturn has been helpful to the astrodynamicist in understanding the effect of the bulge on the orbits of near-Earth spacecraft. By actually observing the variations in the orbits of near-Earth satellites the astrodynamicist has discovered that the Earth has, in fact, an extremely complicated shape. Not only is there a lack of symmetry between the northern and southern hemispheres but there is also an asymmetrical distribution of mass about the Earth's spin axis. The latter means that the equator of the Earth is not circular but is elliptical in shape (approximately 100 m.). It is therefore necessary to represent the gravity field of the earth in terms of a potential expressed in spherical harmonics, which include the zonal harmonics (wrinkles in latitude), the sectorial harmonics (wrinkles in longitude), and the tesseral harmonics (wrinkles in both latitude and longitude). This potential may be expressed as

$$U = -\frac{GM}{r}\sum_{n=0}^{\infty}\sum_{m=0}^{n}\left(\frac{a_e}{r}\right)^n J_{nm}\, P_{nm}\,(\sin\phi)\,\cos m\,(\lambda - \lambda_{nm})$$

where

$$P_n(\sin\phi) = \frac{1}{2^n\, n!}\,\frac{d^n\,(\sin^2\phi - 1)^n}{d\,(\sin\phi)^n}$$

$$P_{nm}(\sin\phi) = \cos^m\phi\,\frac{d^m\,P_n(\sin\phi)}{d\,(\sin\phi)^m}$$

In these equations, G = universal gravitational constant; M = mass of Earth; r = distance from origin of co-ordinates to computation point; a_e = equatorial radius of Earth; ϕ = geocentric latitude; and λ = geocentric longitude.

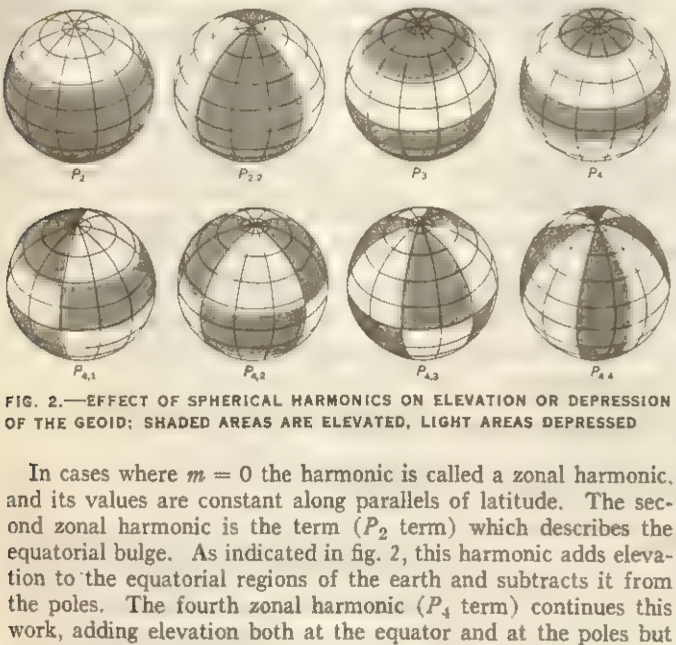

FIG. 2.—EFFECT OF SPHERICAL HARMONICS ON ELEVATION OR DEPRESSION OF THE GEOID: SHADED AREAS ARE ELEVATED, LIGHT AREAS DEPRESSED

In cases where $m = 0$ the harmonic is called a zonal harmonic, and its values are constant along parallels of latitude. The second zonal harmonic is the term (P_2 term) which describes the equatorial bulge. As indicated in fig. 2, this harmonic adds elevation to the equatorial regions of the earth and subtracts it from the poles. The fourth zonal harmonic (P_4 term) continues this work, adding elevation both at the equator and at the poles but slightly depressing the middle latitudes. The proper combination of the second and fourth zonal harmonics will produce a figure that coincides with an ellipsoid within 1 m. Almost all common representations of the earth's figure consider only the second and fourth zonal harmonics. Higher-order even zonal harmonics add to the wrinkles on the earth, remaining symmetric with respect to the equator. The third order zonal harmonic (P_3 term) is the so-called pear-shape term. This term, as with any odd order harmonic, has an opposite effect in the northern and southern hemispheres.

Where $m = n$ the harmonic is called a sectorial harmonic and has values of consistent sign along lines of constant longitude; however, these values change in magnitude as the latitude changes. In addition, for any given latitude the value varies in magnitude and direction as the longitude changes. The $P_{2,2}$ term is the major term indicating that the earth does not have rotational symmetry, and is referred to as the elliptic equator term.

In those cases where $m \neq 0$ and $m \neq n$, the harmonic is called a tesseral harmonic and maintains a value of consistent sign within a tessera, changing sign and magnitude as functions of both latitude and longitude. A tessera is a curvilinear rectangle, in this case bounded by lines of constant longitude and latitude.

Although a satellite may be tracked to an accuracy of 0.1 mi., the lack of knowledge of the gravity field permits prediction of position to an accuracy of only 0.25 mi. per 6 hr. or 1 mi. per day. Thus, even for two relatively simple bodies like a spacecraft and the Earth, the translational motions are complicated because of the complexity of the gravitational force causing them. This same situation also exists for other bodies in space. The Moon, to take an example, is known to be lopsided, and therefore a spacecraft orbiting the Moon will experience similar variations in its orbit.

2. Additional Forces.—In addition to the gravitational force, a spacecraft in its flight around the Earth experiences a drag force due to impact with molecules of air. Furthermore, radiation pressure and a particle wind, originating in the Sun, exert some pressure on the spacecraft and affect the orbit. Additional forces can arise due to the magnetic field of the Earth, as its lines of force are cut by the satellite. All of these forces also must be included in the differential equations for the motion of a spacecraft.

The basic effects of some of these forces are known. The air drag, for example, causes an elliptic orbit eventually to become circular and a circular orbit to decrease in size, with the result that the satellite reenters the atmosphere and either burns up or strikes the Earth. Solar radiation pressures can cause large changes in the altitude of perigee.

B. Three-Body Problem

The simple two-body theory when applied by Newton to the motion of the planets about the Sun verified the excellent observations of Tycho Brahe and the generalizations of Johannes Kepler, except that small variations or perturbations in the orbits were noted. These perturbations in the orbit of one planet about the Sun occurred whenever another planet came near. In a similar manner the orbit of the Moon about the Earth demonstrated appreciable perturbations due to the gravity field of the Sun. It was clear, therefore, that all bodies in space influence all other bodies to some extent, and thus many complicated gravity fields must be considered simultaneously. Even for the relatively simple case of only three bodies, there is no general solution for the equations of motion (*see* Celestial Mechanics).

The situation for a spacecraft is particularly complicated since during some portions of its flight it may be under the strong influence of different bodies and during other portions under weak but simultaneous influences of many bodies. Although the various external forces and gravity fields acting upon a spacecraft may be known approximately and the appropriate equations for the translational motion of the satellite may be set down, no general solutions to the equations are available. Thus the translational motions of the spacecraft would be unknown, were it not for the development of the high-speed computer. The application of the computer by the ballistics scientist to solve projectile trajectory problems has provided the astrodynamicist with an extremely valuable tool that enables him to integrate numerically the complicated equations of motion and, therefore, to arrive at a knowledge of the complete translational motions of a spacecraft. This direct numerical integration is called the special perturbations technique.

If one has a considerable knowledge of the position of the spacecraft as a function of time, it is possible to use the high-speed computer to find special curves which can best represent the observed motions. This process is known as the general perturbations technique.

C. Spacecraft Rotations

Spacecraft injected into orbit without rotation and subject to no external torques will not rotate; the roll, pitch and yaw will all be zero. For spacecraft injected with rotation, the total angular momentum remains a constant if no external torques are present. This characteristic of conservation of angular momentum for spacecraft is fundamental to understanding their rotational performance.

A rotating spacecraft is often subject to small external damping torques, such as magnetic torques arising from the magnetic field of the Earth and air damping torques. There may also be small internal damping torques arising from the movement of components, such as wires, fluids and other masses. The effect of these torques is to cause the spacecraft to change its axis of rotation until it is finally rotating about its axis of maximum moment of inertia. The angular momentum is unchanged when only internal damping is involved. Therefore, spacecraft which are spin-stabilized are designed not as elongated bodies like classical projectiles but rather as somewhat stubby shapes that will fly stably about their initial rolling axis.

Often it is necessary to control actively the angular motion of spacecraft. Again, the fundamental underlying theory is the conservation of angular momentum. The primary control devices are generally small jets to provide torques about the three spacecraft axes. Sometimes internal inertia wheels are used to change the distribution of the angular momentum about each axis.

A special case of the passive control of the angular position of a spacecraft is the use of the gravity gradient torque. This technique is based on the fact that an elongated body in a near-Earth orbit experiences a significant torque due to the difference in the gravity force acting on different parts of spacecraft located at different distances from the centre of the Earth. This torque causes the spacecraft to point its long axis toward the Earth. If, in addition, there exists some damping torque, the spacecraft will be stably Earth-oriented. The gravity stabilization technique is quite reliable because of its simplicity, and there is no limit to its lifetime. It is of special interest for spacecraft used in communications, meteorology, reconnaissance and mapping of the Earth and other planets.

D. Applications

Because the translational motions of a near-Earth satellite are greatly influenced by the complex gravity field of the Earth, and also because there is a need to know the exact locations of satellite tracking stations with respect to each other and with respect to the centre of mass of the Earth, it was recognized that a satellite could be used to determine these quantities. This knowledge, in turn, would make possible both a better understanding of the translational motions of a satellite and an accurate prediction of the orbits of future satellites. Thus, a special geodetic satellite,

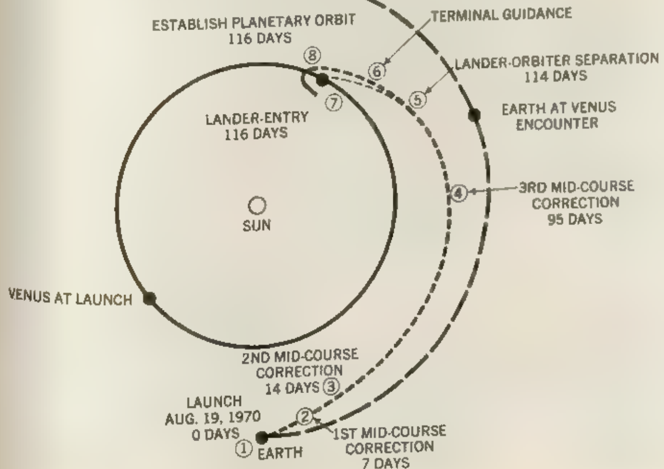

FIG. 3.—TYPICAL TRAJECTORY TO VENUS WITH MANEUVERING POINTS INDICATED

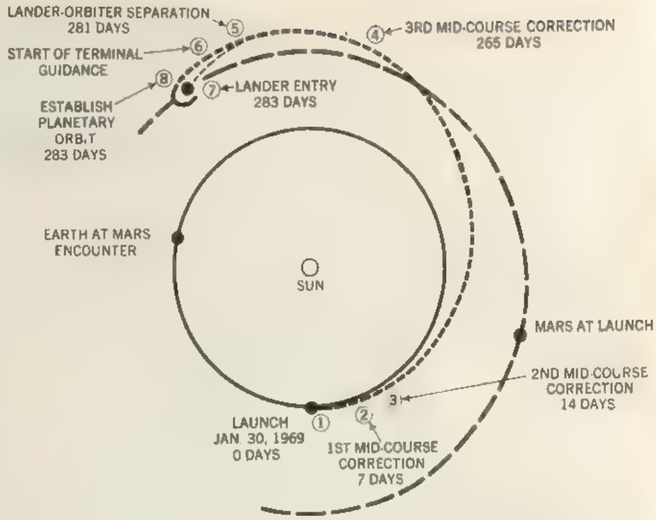

FIG. 4.—TYPICAL TRAJECTORY TO MARS WITH MANEUVERING POINTS INDICATED

ANNA (army, navy, NASA and air force), was conceived and placed into orbit. Various precision tracking techniques, such as optical tracking, doppler tracking, transponder tracking, interferometric tracking and laser tracking, were used to determine: (1) the gravity field of the Earth; and (2) the location of the various tracking stations in geocentric co-ordinates. This was a case, therefore, of a special satellite being used to determine basic astrodynamical information which in turn could be employed to enable a better prediction of spacecraft motion.

Not only is the gravity field of the Earth of interest but also there is considerable interest in determining the gravity fields of the Moon and other planets to enable accurate satellite flight operations in their vicinities. Consider, for example, the motion of a spacecraft traveling from the Earth past Venus. Relative to the Earth the spacecraft travels on a hyperbolic orbit and initially the Earth's gravitational field predominates. However, as the spacecraft moves outward, the Moon's gravitational field becomes dominant over that of the Earth. After passing beyond the Earth-Moon system, the influence of the gravity field of the Sun becomes the primary controlling factor. During its long voyage to Venus (approximately 100 days), the spacecraft follows an elliptical orbit relative to the Sun, subject to small perturbations produced by other planets in the solar system. However, as the spacecraft approaches Venus the gravity field of Venus takes on major importance. Although there is no solution for the translational motions of a spacecraft on such a voyage, the equations of motion may be numerically integrated on a computer and thus the flight path may be obtained (*see* fig. 3 and 4).

In addition, it is necessary to consider the launching energy required to reach a planet when a favourable opportunity is available. As indicated in fig. 5, the favourable opportunities for Mars occur about every 26 months and for Venus about every 19 months. The launching energy, however, is different at each opportunity because of the difference in the geometrical situation. Even at a favourable opportunity there is only a short period (called a launch window) when the energy remains within feasible bounds. It has been shown mathematically that the lowest energy requirement results when it is possible to use what is known as a Hohmann transfer flight path. This simple space maneuver is illustrated in fig. 6. To transfer from the smaller circular orbit to the larger, sufficient velocity is first added in a direction along the orbit to produce a new elliptical orbit with an apogee equal to the radius of the larger orbit. After the satellite has passed along this elliptical orbit and has reached the larger orbit, it is again necessary to add velocity along the orbit to produce the circular orbit at that altitude.

There are also minimum energy transfers for non-coplanar orbits. However, the additional energies are generally quite large. Some of the energy limitations in launching out of the

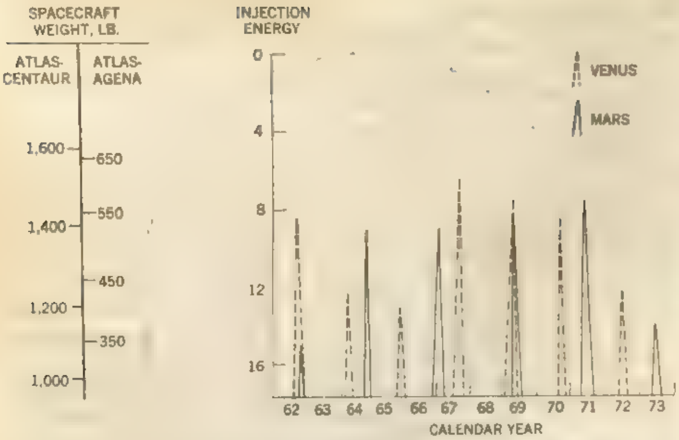

FIG. 5.—PLANETARY ENERGY REQUIREMENTS. RELATIVE ENERGIES IN EXCESS OF ESCAPE ENERGY ARE SHOWN FOR MARS AND VENUS FLIGHTS AT MOST OPPORTUNE TIMES

ecliptic plane are shown in fig. 7. The rays represent inclination to ecliptic plane. The circles represent distance from the Sun in astronomical units (A.U.). For example, a 250-lb. spacecraft launched in the ecliptic plane (0°) can almost reach the Sun (0.08 A.U.). However, if this same spacecraft is launched 37° out of the ecliptic plane it only travels halfway to the Sun.

A voyage of a spacecraft represents a significant breakthrough in the science of astrodynamics. Heretofore, astronomers had only the planets and their motions as a basis for understanding the various gravity fields and the fundamental distances in the solar system. Now man is able to use the spacecraft and their motions in conjunction with those of the planets to obtain a better knowledge of many of the physical constants governing the motion of the planets. For example, a spacecraft flying past the Moon can be used to evaluate both the distance to the Moon and the lunar mass. Similarly, a spacecraft passing near Venus gives trajectory data that can be used to obtain an entirely new estimate of the mass of Venus and the distance from the Earth to Venus. This information, in turn, enables us to obtain a new value for the astronomical unit, which is the fundamental factor for understanding all distances in the solar system and beyond. As a result of the flight of Mariner 2 to Venus and radar observations of the planet, the astronomical unit is estimated to be 149,599,244 km., accurate to within ± 278 km. (*see* Table III).

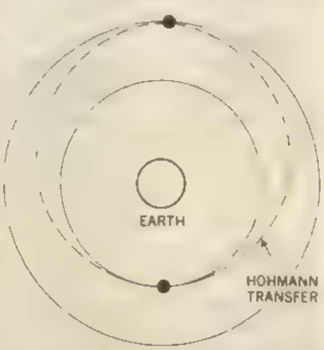

FIG. 6.—SIMPLE SPACE MANEUVER, THE HOHMANN TRANSFER, IN WHICH AN ELLIPTICAL TRANSFER PATH IS EMPLOYED, WITH ENERGY IMPULSES AT PERIGEE AND APOGEE

1. Angular Motion and Controls.—Some examples of the angular motion of spacecraft are as follows: In the case of the Transit navigation satellite it was desired that the satellite not spin in its orbit. However, in order to launch the satellite it was necessary to spin-stabilize the last stage of the launch vehicle. As a result the satellite was placed into orbit spinning. To stop the spin small weights were placed at the satellite's equator. When released, these weights payed out on strings and applied a counterrotating torque to the satellite. In this way most of the angular momentum of the spacecraft was transferred to the weights. The weights were then released into space carrying their share of the spacecraft's angular momentum with them, and the satellite was left with a very small spin.

*Radar determinations

The specifications for the Tiros weather satellite called for a spacecraft which was spin-stabilized and from which pictures of the clouds could be taken, but which would not pitch or yaw. Therefore, internal viscous damping was provided; the viscous torque caused the wobbling motion to damp out and gave a stable rolling motion about the axis of maximum moment of inertia. Such passive angular control has been extremely successful.

Tiros also furnishes an excellent example of a simple technique for changing the orientation of the spin axis of a spacecraft. When a change is desired, an electromagnet in the satellite is activated. This magnet then tries to align itself with the local magnetic lines of force of the Earth and in doing so applies a torque that causes the spacecraft to precess, thereby changing the orientation in space of its spin axis. The electromagnet is turned off once the spacecraft has reached the desired new orientation.

In the case of the Orbiting Astronomical observatory (OAO), inertia wheels will be used to vary the distribution of the angular momentum of the spacecraft about each of its three principal axes. By redistributing this momentum from the spacecraft to and from these spinning wheels, it is possible to control the pointing accuracy of the telescope to fractions of a second of arc.

2. In-Space Maneuvering.—Maneuvers in space are quite different from those on earth. In space a body moves in a curved line, the curvature depending upon the instantaneous location vector and velocity vector of the spacecraft. For example, to apply a trajectory correction (*i.e.*, a mid-course correction) to the Mariner 2 spacecraft, it was necessary to know the future time at which the correction would be made. Furthermore, it was necessary to know accurately the location and velocity of the spacecraft at that time. The change in the velocity vector to place the spacecraft in the new trajectory had to be predicted so that the spacecraft would just miss Venus, which was also moving on a curved path. In addition, the angular orientation of the spacecraft in space had to be known and had to be changed to a new orientation so that the corrective force would be applied in the proper direction. Without going into the details of computation, timing and execution, the complexity of such a maneuver is evident (*see* fig. 5 and 6). Mariner 2 originally was on a trajectory that would have missed Venus by 233,000 mi. After the mid-course correction it missed Venus by 21,600 mi., which was on the safe side and only 11,600 mi. off the intended "bull's-eye miss" of 10,000 mi. Similar techniques were used to establish the Mariner 4 trajectory for the fly-by of Mars in 1965 and to correct the lunar impact or landing positions of the Rangers 7, 8 and 9, and of Surveyor 1. *See* also AERODYNAMICS; BALLISTICS: *Exterior Ballistics*; GEODESY. (Jo. D. N.)

II. LAUNCH VEHICLES

Launch vehicles are powered heavier-than-air craft that are used to place a secondary craft or payload into ballistic trajectory. They are closely akin to their predecessors, the guided missiles or military rockets, which were fashioned to deliver warheads

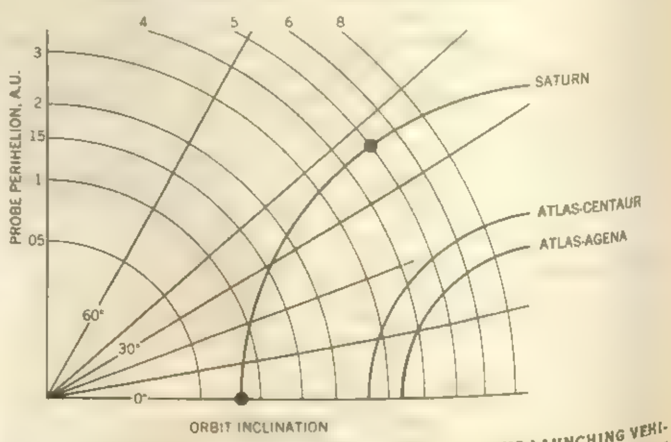

FIG. 7.—NECESSARY BOOSTER PERFORMANCE FOR VARIOUS LAUNCHING VEHICLES TO LAUNCH A 250-LB. SPACECRAFT TOWARD THE SUN AT DIFFERENT ANGLES OUT OF THE EARTH'S ECLIPTIC PLANE

Astronaut Edward H. White as he maneuvered in space more than 100 mi. above the surface of the earth. The 25-ft. "umbilical" line which provided him with oxygen and tethered him to the spacecraft may be seen in this photograph

THE FLIGHT OF GEMINI 4

The flight of Gemini 4 in June 1965 lasted 97 hours and 56 minutes, during which the spacecraft containing United States astronauts James A. McDivitt and Edward H. White II made 66 orbits of the earth. During the third orbit, as Gemini 4 swept toward the Pacific coast of the United States, astronaut White emerged from the spacecraft and floated in space for about 22 minutes. Photographs of the first man to float in space, Soviet cosmonaut Alexei Leonov, may be found on the following plate

against military targets. Launch vehicles, however, must be capable of greater flexibility to perform a variety of tasks.

1. History.—Scientific uses for rockets were suggested by Konstantin Tsiolkovski of Russia in his treatise on space travel (1903). Robert Goddard of the United States launched the first rocket vehicle employing a liquid-fueled rocket engine on March 16, 1926. The fast technological growth in aeronautics during the 1930s and 1940s was effectively adapted to rocket technology to produce the V-2 in Germany (1938–45), the first supersonic aircraft, X-1 in the United States (1947), and a series of ballistic missiles. The perfected state of guidance and control systems was a most essential part of this rapid utilization of rocket power. (*See* also ROCKETS AND GUIDED MISSILES.)

2. Configurations.—Launch vehicles usually consist of one or more rocket-powered stages utilizing precise guidance systems in conjunction with control systems that actuate steering mechanisms. Small sounding rockets and upper stages of larger vehicles are sometimes stabilized in a fixed orientation by spin imparted from auxiliary power sources or by canted aerodynamic fins.

The airframe of a launch vehicle is closely integrated with the propellant tanks, which make up most of the vehicle's volume. Propulsion is most commonly supplied from rocket motors operating on the reaction forces produced from the high-pressure combustion of liquid fuel and liquid oxidizer combinations or from solid combustibles. Propulsion produced from the combustion of a fuel with the oxygen of atmospheric air, such as the ramjet, is not suitable for application to space launch vehicles.

3. Guidance.—Guidance systems are composed of several basic elements which provide: (1) continuous flight information for the determination of vehicle position, velocity and angular orientation; and (2) computations based on this information for appropriate control commands. Guidance elements can be located both in the vehicle and on the ground. When all guidance elements are in the vehicle the system is referred to as "all-inertial," and guidance accuracy depends upon the precision of inertial sensors that provide the reference for measurement of position and orientation. These systems, being insensitive to external influences (*e.g.*, radio jamming), are usually employed in military missiles. Nonmilitary vehicles more commonly employ ground-based equipment in conjunction with the airborne elements in order to increase flexibility, performance and accuracy.

4. Launch Facilities.—Final launch vehicle flight preparation is accomplished at a range which provides checkout, propellant, photographic, calibration, tracking, telemetry, timing and safety services. Ranges in use in the 1960s included: (United States) Eastern test range, Cape Kennedy, Fla.; Western test range, Lompoc, Calif.; White Sands missile range, N.M.; Wallops station, Wallops island, Va.; (France) missile centre and test range near Arcachon, southwest of Bordeaux; Colomb-Béchar, Alg.; Levant Island range, south of Toulon; Papeete range in the South Pacific, Tuamotu archipelago; (U.S.S.R.) Kapustin Yar, southeast of Volgograd; Aral'sk on the Aral sea; Franz Josef Land in the Arctic; Mirny in Antarctica; (Canada) Fort Churchill; (Japan) Akita rocket range, in northwestern Honshu; Kagoshima space centre, southern Kyushu; (Australia) Woomera.

5. Operation.—Vehicles are usually launched vertically and so maneuvered in roll, pitch and yaw as to produce the proper final trajectory. Multi-stage vehicles can conveniently make use of coasting periods or parking orbits to change the flight direction in pitch. Trajectory analysis is a highly specialized art requiring extensive use of trained personnel and automatic computation.

6. Vehicle and Spacecraft Communication.—Range-based facilities usually provide for the required vehicle tracking and data acquisition (telemetry) associated with launches. Vehicles spending long periods of time in powered flight or in parking orbits frequently need tracking and data services from bases located away from the launch sites. These bases are linked to a common information centre by a radio and landline network.

The demands for data and tracking information over extended periods of time are met by several established networks. NASA organized three such networks for nonmilitary missions: the Earth Satellite network, the Manned Space Flight network and the Deep Space network. Responsibility for the development, implementation and operation of the major tracking and data acquisition networks for the manned and unmanned satellite programs was assigned to the Goddard Space Flight centre, Greenbelt, Md. The Jet Propulsion laboratory, Pasadena, Calif., is responsible for the Deep Space network. Stations for the Earth Satellite network were established at 14 locations on 5 continents. The Smithsonian Astrophysical observatory, Cambridge, Mass., operates a worldwide optical network in support of certain scientific satellites.

Primary unmanned satellite tracking is based to a large extent upon interferometric systems operating in a radio frequency band of 136–137 mc. Telemetry data are acquired by means of high-gain antenna systems located at data readout stations. The telemetry information is usually recorded on magnetic tape.

Manned spacecraft tracking is done by radar because of the

usually low orbits associated with these missions. The Deep Space network consists of three instrumentation stations with large steerable "dish" antennas spaced around the world to provide continuous surveillance of lunar and planetary spacecraft.

7. Launch Vehicle Characteristics.—A single-stage vehicle operating under conditions of zero gravity and drag will acquire a velocity gain in the direction of thrust according to the classic rocket equation, $\Delta v = Ig \cdot \ln (m_i/m)$, where Δv is the ideal stage velocity increase; I is the specific impulse of the propellant combination used in the rocket motor and is equal to rocket thrust divided by propellant flow; g is gravitational acceleration (standard); m_i is the stage mass at initiation of rocket thrust; and m is the stage mass at rocket thrust termination.

The quantity Ig, possessing the units of velocity, is the "effective exhaust velocity" of the rocket. It serves as a measure of propellant effectiveness. Characteristic values for Ig extend from 7,000 to 14,000 ft. per second; values in the 9,000–10,000 range are commonly attained in practice. The masses m_i and m contain the inert or tare weights of the payload or spacecraft. Elimination of the latter results in m_i/m being the mass ratio of the stage, this term then being a measure of the structural efficiency of the stage designs. Values for m_i/m of 5 to 10 are common. Lower values are associated with rigid propellant tank designs and the higher numbers with pressure-stabilized designs.

Because of the logarithmic character of the rocket equation, it is convenient to use a logarithmic scale for the payload on these performance charts. For multi-stage vehicles the ideal velocity is the sum of the ideal velocities of the stages. Thus,

$$V_i = \{Ig \cdot \ln (m_i/m)\}_1 + \{Ig \cdot \ln (m_i/m)\}_2 + \dots$$

In actual practice, velocity is lost because of gravitational and aerodynamic forces. These losses are heavily dependent upon the characteristics of the vehicle and the particular trajectory flown, and the computation of them is complicated. (R. B. M.)

III. SPACECRAFT

Tables V and IX list some of the spacecraft successfully launched since the beginning of the space age in 1957. Over the years the number and rate of successes increased steadily, the percentage for the U.S. rising from 29% in 1958 to about 90%.

A. Function

The purpose of the spacecraft is to carry a cargo into space, and sometimes to bring the cargo back to Earth. The cargo may be instruments or it may be man with his instruments. In this section only automated spacecraft will be discussed; *see* also *Manned Space Flight*, below.

The spacecraft must provide the environment and services required for the instrumentation ("instrumentation" here refers to the equipment associated with experiments, measurements, etc., to be made by the spacecraft; *e.g.*, radiation sensors, television cameras and micrometeor counters). With respect to environment, it is necessary to maintain the proper temperature, pressure, vibration level, rigidity and thermoconductivity. With respect to services, it is necessary to supply: (1) a structural platform; (2) power, both electrical and propulsive; (3) communications; (4) a diagnostic monitoring system for determining the condition of the spacecraft; (5) a command centre for channeling various command signals to the various types of instrumentation aboard; and (6) a control centre for guidance and navigation of the spacecraft.

In general the environment and services required by instrumentation are quite similar from one spacecraft to another. However, the instrumentation itself may differ widely in character and function. At one extreme may be a scientific satellite carrying delicate and sophisticated instrumentation for precision measurement and at the other extreme may be a simple transmitter, as in the first Vanguard satellite.

B. Typical Spacecraft

Some typical spacecraft will be described in order to illustrate their diversity and some of their design details.

1. Atmospheric Structure Satellite.—The Atmospheric Structure satellite (Explorer 17) was a 405-lb. spacecraft carrying instruments to measure the density, composition, pressure and temperature of the atmosphere. The spacecraft was a hermetically sealed sphere designed to be nearly leakproof, thus minimizing contamination of the atmosphere of space. For example, at apogee the internal satellite pressure was 10^{13} times greater than the "hard vacuum" of space on the outside; any gas leakage from the spacecraft would interfere with measurements of the tenuous space environment.

Electrical energy to the spacecraft was supplied by approximately 150 lb. of silver-zinc chemical batteries. With all instrumentation operating, the satellite consumed 110 w. of power and could operate at this load for about 70 hr. Since there was no provision for data storage aboard the spacecraft, and since satellite "turn-ons" were to last about 5 min., several hundred data "passes" could be obtained. A reasonable useful lifetime of the satellite was computed at between two and three months (the actual lifetime was 99 days).

When injected into orbit, the satellite was spin-stabilized at 1.5 cycles per second. An inclination of 58° from the equator gave it a coverage of the Earth's surface to within several degrees of the arctic and antarctic regions. The orbital period was 90 min. The spacecraft carried an aspect system to determine the orientation of its spin axis in relation to a reference plane; this information was needed to allow the experimenters to interpret their data correctly. A four-component aspect system was used, comprised of a digital-fan sensor, a slit-fan sensor, a Sun-Moon switch and two infrared Earth sensors. The system was designed to use the Earth and either the Sun or the Moon as references against which to locate the satellite spin axis. A digital-fan sensor uses an optical masking technique and six photodiodes to measure the angle of a light source viewed by the sensor. The slit-fan sensor, located in the same housing as the digital fan, is used to measure azimuth angles accurately.

The Sun-Moon switch reduced the gain of the amplifier when sunlight was viewed and restored full gain when the Moon was the reference object. The two Earth sensors had a pencil beam of approximately 2° solid angle and were mounted in the same housing. One sensor had an elevation of 22° north of the equator of the satellite, and the other pointed 22° south of the equator. These Earth sensors operated in the 7–15 micron infrared wavelength region and detected the discontinuity at the Earth's horizon. Prior to launch, steps were taken to insure that the satellite was stable about its predetermined axis of rotation. The battery and electronics components were distributed to ensure maximum moment of inertia about this axis.

The Atmospheric Structure satellite was the first scientific Earth satellite containing a pulse-code modulation (PCM/FM) telemetry system. Previous satellites used the pulse-frequency modulation (PFM/AM) system. The solid-state PCM system provided an output power of 500 mw. and was capable of supplying 40 separate channels of information in digital form.

Provisions were made to permit selection of experiments while the satellite was in orbit. Two command receivers were used, each capable of two independent commands. The number of allowable combinations permitted resolution of possible interference between the various detectors. While equipment "turn-on" was controlled from the ground, "turn-off" of all equipment was automatic and produced from on-board instrumentation, ensuring that power would not be wasted when the satellite passed out of the range of the command receiver.

2. Interplanetary Explorer.—The Interplanetary Explorer (Explorer 18) is a 138-lb. spacecraft placed into a highly elliptical orbit: an apogee altitude of 122,800 mi., a perigee of 120 mi. and an inclination to the equator of 33°, corresponding to an orbital period of approximately four days. The spacecraft is designed to study interplanetary radiation and magnetic fields in the vicinity of the Earth and Moon. Explorers 21 and 26 are also Interplanetary Explorers.

Explorer 18 is an octagon-walled platform, 28 in. across and 12 in. deep, fabricated from nylon honeycomb and fibreglass. A

FIG. 8.—ORBITING SOLAR OBSERVATORY, FIRST LAUNCHED SUCCESSFULLY IN MARCH 1962

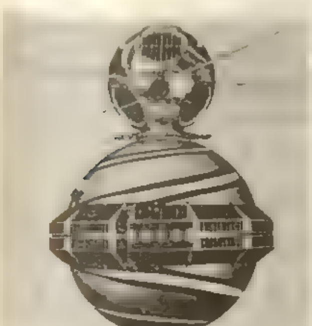
rubidium-vapour magnetometer is located on a 71-in. boom on top of the platform and two fluxgate magnetometers on 14-ft. booms at the sides. Four spring-loaded solar-cell paddles extend from the main structure to supply the required power.

The satellite transmits data continuously during its operating time in orbit on the 136.110 mc. frequency; signals from the 1.5-lb. 4-w. transmitter can be received by NASA stations at distances of 123,000 mi. Data are recorded 100% of the time for approximately the first six months of flight, and then for 25% during the remainder of the satellite's lifetime. The telemetry system is designed so that the recorded data can be processed 16 times faster than real time.

3. Orbiting Solar Observatory.—The Orbiting Solar observatory (OSO) is a 500-lb. spacecraft designed to accommodate interchangeable experiments for studying the Sun. A weight of about 250 lb. is allotted for the total experiment payload.

The OSO consists of two sections: a nine-sided wheel composed of wedge-shaped compartments and a semi-circular section, mounted above the wheel, called the sail. When the spacecraft is in orbit, three arms extend from the wheel and slow its rotation to about 30 r.p.m.; the arms can be used as antennas. The wheel diameter is 44 in. Five of the nine wedge sections, each with a volume of approximately 1,000 cu.in. and a maximum weight capacity of 30 lb., are available for experiments. When in orbit, the wheel rotates much like a gyroscope, each section facing the Sun every two seconds.

The sail, joined to the wheel by a rotating shaft, is designed so that it aims always at the Sun. The sail carries an array of solar cells to supply power and recharge batteries that produce about 16 w.; of this, 9 w. is available for power experiments. In addition, the sail carries two compartments for experiments which must point at the Sun; each is 4 × 8 × 36 in. and is able to carry approximately 50 lb. of equipment, but the two may be combined to give double the space and weight capacity.



BY COURTESY OF U.S. NAVY

FIG. 9.—TRANSIT 2A/NRL SATELLITE LAUNCHED JUNE 22, 1960, FROM CAPE CANAVERAL (NOW CAPE KENNEDY), FLA.

Data from each experiment are stored sequentially in digital form on a tape recorder operating continuously throughout each 95-min. orbit. The information from the recorder is read out at high speed on command from a ground station. The first OSO was launched in 1962, the second early in 1965 and the third in mid-1965.

4. Transit.—Transit (fig. 9.) is a satellite weighing approximately 135 lb. It is designed to provide navigational data to military and civilian ships. The spacecraft has an octagonal body of fibreglass and honeycomb plastic, 12 in. high and 18 in. across. Four panels containing 18,000 solar cells are mounted on the sides, and the power these produce is stored in nickel-cadmium batteries. The spacecraft employs gravity-gradient stabilization, utilizing a single self-erecting boom equipped with a long fine-damping spring with a small mass on the end. The primary instrumentation consists of two ultrastable oscillators operating at 150 and 400 Mc.

5. Mariner.—The Mariner spacecraft (Mariner *2*) weighed 447 lb. and was launched by an Atlas-Agena vehicle in a 180,000,000 mi., 109-day trajectory past Venus. The spacecraft (fig. 10) was 5 ft. in diameter at the base and 9 ft. 11 in. high. In the cruise position, with solar panels and high-gain antenna extended, it was 16.5 ft. across and 11 ft. 11 in. high.

The design was a variation of the hexagonal concept used for the Ranger series. The base housed a liquid-fuel rocket motor for trajectory correction and six modules containing the attitude control system, electronic circuitry for the scientific experiments, power supply, battery and charger, data encoder and command subsystem, digital computer and sequencer, and radio transmitter and receiver. Sun sensors and attitude control jets were mounted on the exterior of the base.

A tubular superstructure extended upward from the base and scientific experiments were attached to this framework. An omnidirectional antenna was mounted at the peak of the superstructure. A parabolic, high-gain antenna was hinge-mounted below the base, and two solar panels also were hinged to the base; these folded up alongside the spacecraft during launch, parking orbit and injection phases, and unfolded like butterfly wings when the craft was in space. A command antenna for receiving transmissions from Earth was mounted on one of the panels.

Two-way communication aboard the Mariner *2* was supplied by the receiver/transmitter, two transmitting antennas (the omnidirectional and high-gain antennas) and the command antenna for receiving instructions from Earth. The spacecraft transmitting power was only 3 w. An Earth sensor was mounted on the antenna yoke near the rim of the high-gain, dish-shaped antenna to search for and keep the antenna pointed at the Earth.

Stabilization of the spacecraft for yaw, pitch and roll was provided by ten cold-gas jets mounted in four locations and fed from two titanium bottles containing 4.3 lb. of nitrogen at 3,500 p.s.i. The jets were linked by logic circuitry to three gyroscopes in the attitude-control subsystem, to the Earth sensor on the parabolic antenna, and to six Sun sensors mounted on the spacecraft frame and on the backs of the two solar panels.

On July 14, 1965, seven and a half months after its launch, Mariner 4, a successor of Mariner *2*, flew past Mars to become the first spacecraft to make a successful journey to that planet. After its Mars encounter, Mariner 4 continued to return data on the interplanetary environment until Oct. 1, 1965. In 1967 it will pass within about 29,000,000 mi. of the Earth, and during that time it should be possible to again obtain data from the spacecraft.

All Mariner spacecraft carried a set of instruments designed to measure the fields, radiation and particles of interplanetary space. There were about twice the number of nuclear particle detectors installed on Mariner 4 as could be accommodated by Mariner 2. The vector magnetic fields, measured by a flux-gate magnetometer on Mariner 2, were detected by a more sensitive molecular resonance magnetometer on Mariner 4. The instrument for measuring the micrometeoroids of interplanetary space on Mariner 4 has been similarly improved. The large quantity of precise orbital data obtained during months of tracking Mariner 4 as it moved away from the Earth provided a basis for significant improvements in man's knowledge of certain fundamental physical constants of the solar system.

Most of the Mariner interplanetary instruments and investigations are useful in exploring the target planet. In addition, the spacecraft carried special instrumentation for planetary measurements. Since Venus is enshrouded in clouds and because of the payload weight limitations imposed on the Mariner 2 design, the planetary instruments on this spacecraft were limited to radiometers capable of spatially resolving the temperatures of Venus. The planetary instrument on Mariner 4 was a television camera, which obtained 22 pictures of the Martian surface. An extension

TABLE V.—*Advances in Space Exploration by Unmanned Artificial Satellites and Space Probes*

Name	Nation	Launched	Launch vehicle	Perigee/Apogee (mi.)	Period (min.)	Lifetime*	Weight in orbit† (lb.)	Remarks

FIG. 10.—A MODEL OF THE MARINER 2 SPACECRAFT WHICH WAS LAUNCHED AUG. 27, 1962, ON A COURSE WHICH CARRIED IT TO WITHIN 21,600 MI. OF VENUS. ITS MISSION WAS SUCCESSFULLY COMPLETED DEC. 14, 1962, WITH THE RADIOING OF MESSAGES BACK TO THE EARTH. THE MODEL IS SHOWN WITH ITS SOLAR PANELS EXTENDED IN CRUISE POSITION

in the application of precision tracking data obtained in the region of the planet provided more accurate knowledge of the mass and atmosphere of Mars.

Both spacecraft utilized two celestial references for three-axis stabilization—for Mariner 2, the Sun and the Earth, and for Mariner 4, the Sun and Canopus. Both spacecraft also contained a mid-course guidance rocket and obtained their electrical energy from silicon cells. Mariner 4 was larger and heavier than Mariner 2. With solar panels extended and solar pressure vanes opened, it spanned more than 22 ft.—about 6 ft. more than Mariner 2. In the dimension from the top of the omnidirectional antenna to the bottom of the base structure, both spacecraft measured about 10 ft. Mariner 4 weighed 575 lb., approximately 125 lb. more than Mariner 2, and contained almost 140,000 individual parts. The most obvious differences between the two spacecraft were in the number of solar panels, the shape of the base structure, the construction of the omnidirectional antenna masts and the locations of the directional antennas and planetary instruments.

The basic structure of Mariner 4 was a 30-lb. octagonal magnesium framework with seven electronics compartments and a mid-course rocket propulsion system around the perimeter. The compartments themselves provided structural support to the spacecraft. Four solar panels, each 71.4 in. long and 35.5 in. wide, were attached to the top, or sunward side, of the octagon.

Because the Mars mission carried the spacecraft away from the Sun, additional solar cell area had to be provided for Mariner 4. About 28,200 semiconductor cells were mounted on the four panels, and—except during launch and maneuvers—they provided the primary source of electrical power to the spacecraft. The attitude-control gas jets and the active solar vanes, which stabilized the spacecraft relative to the direction of the Sun, were mounted on the ends of the panels. The electrical energy originating in the Mariner 4 solar panels flowed into a pair of power regulators, either one of which could assume the full electrical load.

The interior of the octagon contained gas bottles and regulators for Mariner's dual-attitude control gas system. The propellant tank for the liquid-fuel mid-course motor is supported by a cantilever arrangement inside the octagonal cavity, with the rocket nozzle protruding through one of the eight sides. Two sets of attitude-control jets consisting of six jets each, which controlled the spacecraft on three axes, were mounted on the ends of the solar panels near the pressure vane actuators.

The high-gain antenna was attached to the spacecraft by an eight-legged superstructure atop the octagon. Its aluminum honeycomb dish reflector is an ellipse, 46 by 21.2 in., and is parabolic in cross section. The antenna, which weighed only 4½ lb., was in a fixed position. The low-gain omni-antenna was mounted on the end of a circular aluminum tube, 3.88 in. in diameter and extending 88 in. from the top of the octagonal structure. The tube acted as a wave guide for the low-gain antenna.

The Canopus star tracker assembly was located in the shade of the spacecraft on the lower ring structure of the octagon for a clear field of view. Sun sensors were located on both the top and bottom surfaces of the spacecraft body in order to provide spherical coverage.

6. Orbiting Geophysical Observatory.—In 1964, the first Orbiting Geophysical observatory, OGO-1, was launched into an elliptical orbit about the Earth. This type of spacecraft is larger than the Explorer class, weighing somewhat more than 1,000 lb. and designed to accommodate up to 50 individual experiments.

It is designed to be stabilized by motor-driven inertial flywheels and gas jets to keep one face toward the Earth, maintained so that one axis in the spacecraft is always along the line to the centre of the Earth. The solar paddles were designed to face continuously toward the Sun to ensure maximum power. The payload from an OGO consists primarily of experiments selected to make co-ordinated measurements and observations of many aspects of the Earth environment simultaneously in order to supply a clearer picture of the relationships between them and their dependence upon solar activity. Two types of OGO's are scheduled to be used. The EGO, or Eccentric Orbiting Geophysical observatory, such as OGO-1, is planned to have a highly elliptical orbit reaching beyond the Earth's magnetic field or magnetosphere into the near-Earth interplanetary space.

The POGO, or Polar Orbiting Geophysical observatory, will be placed in a low-altitude orbit over the poles for studies primarily of the upper atmosphere and the ionosphere, and for monitoring incoming radiations.

The OGO is essentially a boxlike structure, 6 × 3 × 3 ft. in size, of aluminum sandwich panels, that houses the scientific instrumentation and the equipment needed for power, telemetry, communications and attitude control. Projecting from the box are antennas for communications, booms for experiments requiring separation from the spacecraft and the other experiments, a boom

and containers for experiments that require alignment in the orbital direction, two paddles of 75 sq.ft. combined area that carry the solar cells, an antenna for the radio astronomy experiment and experiments that must point to the Sun. In orbit OGO-1 resembles a giant insect with a 20-ft. wing spread. OGO-2 and 3 launched in Oct. 1965 and June 1966 were basically similar.

7. Ranger.—Ranger 7, an 806-lb. spacecraft, was launched toward the moon by an Atlas-Agena B rocket on July 28, 1964. The mission of Ranger was to take photographs of the moon before impacting on its surface. The tubular-shaped craft was equipped with two "wings" that extended from the bottom of the main tower structure at approximately right angles; these wings, constructed so that they would face the sun during flight, contained panels of solar cells that converted the sunlight into the electricity needed to power the craft's equipment. Six television cameras mounted in the tower of Ranger focused on the moon through an aperture in the centre of the tower. At the top of the tower was an omnidirectional antenna used during launch and in a mid-course maneuver. Facing away from the moon and toward the earth was a dish-shaped antenna that transmitted the photographs.

During the last 17 minutes of its flight Ranger returned more than 4,000 high-resolution photographs of the moon's surface, the last at an altitude of about 1,600 ft. Rangers 8 and 9 later successfully performed similar missions.

8. Surveyor.—The Surveyor 1 spacecraft was launched on May 30, 1966, from Cape Kennedy on a mission to land intact ("soft-land") on the Moon's surface. Approximately 16 hr. after launch, a successful mid-course correction maneuver was executed, moving the landing point to an area north of the crater Flamsteed in the Ocean of Storms. Because telemetry indicated that one of the two omnidirectional antennas may not have fully deployed, a terminal maneuver was used which assured correct Earthward orientation of the deployed antenna during descent. The spacecraft properly executed all commands and landed successfully on June 2, 1966. Preliminary data indicates that it touched down at a vertical velocity of approximately 10 ft. per second.

During its first 12 days of operation on the Moon, Surveyor 1 transmitted more than 10,000 pictures. They indicated that the spacecraft had landed on a dark, relatively smooth, bare surface, encircled by hills and low mountains and that the terrain within 1 to 2 km. surrounding the landing site is a gently rolling surface studded with craters with diameters ranging from a few centimeters to several hundred meters and littered with fragmental debris ranging from less than 1 mm. to more than 1 m.

The configuration of the Surveyor spacecraft is shown in fig. 11. The basic structure, which provides mounting surfaces and attachments for the power, communications, propulsion and flight control systems, as well as a platform for the payload packages, is constructed of thin-walled aluminum tubing with the members interconnected to form a triangle. A shock-absorbing landing leg is attached by a hinge to each of the three lower corners of the structure. The legs were folded into a nose fairing during launch. As additional protection against landing loads, blocks of crushable aluminum honeycomb were placed on the bottom of each corner of the frame. A vertical mast with mechanisms that position the high-gain planar array antenna and solar panel was mounted on top of the structure. The basic frame weighed less than 60 lb. and the installation hardware weighed 23 lb.

Surveyor 1 was about 10 ft. high, and its tripod landing gear fitted just within a circle 14 ft. in circumference. Weighing 2,194 lb. at launch, the spacecraft had a landing weight of 596 lb. after depletion of propellants and other consumables and after jettison of the altitude-marking radar and the main retrorocket casing.

FIG. 11.—(LEFT) MODEL OF U.S. SPACECRAFT SURVEYOR 1 (WITHOUT MAIN RETROROCKET), WHICH MADE A SUCCESSFUL LUNAR LANDING IN JUNE 1966. SPACECRAFT IS 10 FT. HIGH AND WEIGHS 596 LB. WITHOUT FUEL. (ABOVE) PHOTOGRAPH OF THE MOON'S SURFACE TAKEN FROM SURVEYOR 1 SHOWS CRATER AND ROCK 6 IN. HIGH

Two thermally controlled compartments, their temperatures held within acceptable limits by a careful arrangement of absorptive and reflective paints, by conductive heat paths and thermal switches and, on the dark side, by small electric heaters, were provided aboard the spacecraft. One compartment, its temperature maintained between 40° and 125° F., housed communications and most power-supply electronics. The other, held between 0° and 125° F., housed the command and signal processing functions. The solar panel, consisting of a series-parallel array of 792 solar-cell modules approximating 9 sq.ft. in area, supplied up to 85 w. of power during the flight and on the lunar surface. Rechargeable silver-zinc batteries were used for energy storage and to accommodate peak loads.

Inertial references for detecting and controlling the attitude of the spacecraft during cruise flight, as well as during mid-course and terminal maneuvers, were provided by a Canopus star tracker, a Sun sensor and rate gyros on three axes. During cruise flight, attitude control was exercised by a subsystem employing small cold-gas thrusters. Control during descent was exercised initially by the autopilot, vernier engines and by an altitude-marking radar that began the firing of the main retrorocket. Subsequently the spacecraft was steered and decelerated by velocity-measuring and altimeter radars that, in conjunction with the on-board analog computer, autopilot and vernier engines, provided automatic closed-loop guidance for the final descent.

Two propulsion systems were used by Surveyor 1. The main retrorocket employed a solid propellant in a spherical steel case. Its thrust was of the order of 8,000 to 10,000 lb., depending upon temperature. The second, or vernier, propulsion system used hypergolic liquid propellants. Three throttleable thrust chambers were used, each capable of delivering from 30 to 104 lb. of thrust as required by the flight-control subsystem. One chamber could be swiveled for roll control. The vernier engines were used for the mid-course maneuver and in the terminal landing sequence.

For communications, Surveyor 1 carried two transmitters, two receivers, two omnidirectional antennas and the planar-array high-gain antenna, used for transmission of the 600-line television pictures. Tracking and engineering data were transmitted continuously on a frequency of 2,295 Mc. at a power of 10 w. The radio link also incorporated decoders that addressed commands received from Earth to the proper subsystems aboard the spacecraft, and signal processors that conditioned various data signals for transmission back to Earth.

The survey television camera aboard the spacecraft transmitted

200- and 600-line pictures of the lunar surface on command from Earth. The vidicon tube and its shutter, diaphragm and optics were mounted almost vertically and were surmounted by a mirror that could be adjusted both in azimuth and elevation by stepping motors. Provision was also made for remotely inserting filters in the optical system, to permit colorimetric evaluation of individual pictures. The focal-plane shutter of the camera, normally providing an exposure time of 150 milliseconds, could also be held open for longer intervals on Earth command. A lens of variable focal length was used, covering a field of 6.4° by 6.4° at its maximum focal length of 3.9 in. and a field of 25.4° by 25.4° in its wide-angle focal length of 0.98 in. The focus distance of the lens could also be commanded to cover a range from 4 ft. to infinity; and the diaphragm, though adjusted automatically, could also be set by command from Earth.

In addition, more than 100 items of engineering instrumentation were carried by Surveyor 1, and their readings were telemetered to Earth. They included temperature sensors, strain gages, accelerometers and position-indicating devices. The weight of this engineering payload, including an auxiliary battery, was 63.5 lb.

C. Spacecraft Design

The paramount requirements in spacecraft design are reliability and long life; the spacecraft must work, and it must work for a long time. The total cost of a particular development program depends directly on the ability of the designer to fulfill these requirements. A satellite that works for a long time collecting desired data clearly obviates the need for additional spacecraft to collect the same data, and therefore saves additional fabrication and launching costs. Reliable long life, therefore, is the keystone to success in spacecraft technology, not only for near-Earth orbits but especially for spacecraft journeying to other planets. A trip to Mars, for example, takes almost a year, and during that time the spacecraft must be capable of performing guidance and navigation functions as well as scientific measurements. If it is to land when it finally reaches Mars, it must then be capable of operating on the surface. A Martian year is about two Earth years. Therefore, the requirement for long life, completely unattended by human hands, is the great challenge that faces the designer of automated spacecraft.

The first essential for success is simplicity, a feature exhibited by some of the early satellites. They tended to be spherical so that the drag forces would be nearly constant and the resultant orbits could be more readily computed and tracked. They had simple power supplies such as storage batteries or small banks of solar cells to utilize the energy coming from the Sun. Their transmitters and associated electronic circuitry were elementary. That this simplicity of design was successful is evident in the case of the Vanguard satellite, which operated continuously in orbit for over five years.

D. Spacecraft Testing

The importance of skilled workmanship and strict quality control in spacecraft construction is obvious. However, it is well known that reliability greatly decreases as the number of components and complexity of design increase. To achieve success in complex satellites, it has been necessary to develop extensive facilities for testing spacecraft before they are launched.

Fundamentally, successful spacecraft performance depends upon: (1) simple, sound design; (2) highly skilled workmanship; (3) strict quality control; (4) mechanical acceleration and vibration tests; (5) thermal and vacuum tests; (6) radiation tests; (7) guidance and control tests; and (8) complete in-flight monitoring of performance.

1. Acceleration and Vibration Tests.—Every satellite must endure and survive the rugged accelerations and vibrations imposed during launch, so testing facilities that simulate these stresses have been developed. The launching accelerations are simulated by a centrifuge. The accelerations during launch can be programmed, and the spacecraft can be mechanically, structurally and elastically examined in detail under simulated conditions.

A vibration machine is used to pinpoint those resonances that may produce structural failure or distortion. Just as wind-induced resonances can destroy a large suspension bridge, so small vibrations can cause solar paddles, antennas and the main structural components of a satellite to fail. Vibration tests have been extremely important in uncovering weak points in mechanical design that otherwise might not be discovered. About 30% of the spacecraft failures occur during the vibration test.

2. Pressure and Temperature Tests.—An important hazard to spacecraft performance is the low pressure in outer space. Some components, for example, might blow up when placed in a vacuum; some materials might simply evaporate or lose their normal characteristics. The vacuum of space is considerably lower than vacuums readily achievable on Earth, and, therefore, it has been necessary to improve vacuum apparatus. In the mid-1960s vacuum chambers capable of housing complete spacecraft could attain pressures of 10^{-6} mm. of mercury and sometimes as low as 10^{-8}. For small components lower pressures were available.

Temperature presents another problem, for a spacecraft receives heat by radiation directly from the Sun, without the shielding effect provided by the Earth's atmosphere. The amount of heat depends upon the thermoconductivity and the radiation characteristics of the satellite. The temperature of the spacecraft depends upon the heat it absorbs and, in particular, on the heat it radiates away. It is necessary to achieve a good thermal balance in order to minimize extremes of temperature, and it is also desirable to achieve slow changes in temperatures, when changes are unavoidable. Temperature has a direct effect on the lifetime of electronic components; in general, the higher the temperature the poorer their reliability and the shorter their lifetime. Sudden changes in temperature are also serious because they introduce thermoworking and thermofatigue, phenomena that can lead to failure in components and circuitry. The temperature, the radiation and the thermal balance characteristics of spacecraft are thoroughly explored on Earth in thermal chambers, usually combined with vacuum chambers. Heat from simulated "suns" is directed at the satellite. The walls of the test chambers are cooled to the black-body temperatures of space by refrigerants. The satellite itself may be oriented in a systematic manner with respect to the "sun" in order to simulate its flight plan in space. Thermocouples distributed throughout the satellite measure the transient flow of heat and internal distribution of temperatures under various working conditions. In this way "hot spots" may be detected and eliminated.

3. Radiation Testing.—Another problem is that of the intense radiation in space. Radiations coming from the Sun, as well as from the cosmos, pose a special hazard to the performance and life of electronic components, as well as to the characteristics of some structural materials. Solar cells, transistors, resistors, etc., are all subject to serious damage from radiation, particularly during severe solar storms. Artificial radiation also occurs in space as a result of high-altitude explosions of nuclear bombs. Facilities were being constructed in the 1960s to test satellite components and complete spacecraft in strong radiation environments.

4. Guidance and Control Testing.—If spacecraft are to be properly controlled in space, there must be testing facilities on Earth to first prove out the entire guidance and control servomechanism. An excellent approach is to mount the complete spacecraft so that it is free in all three modes of angular motion (roll, pitch and yaw). In this way the servomechanism can be programmed and the spacecraft can be put through various maneuvers. At the same time the system can be placed in a thermo-vacuum chamber and can be operated for long periods to determine its lifetime in the space environment. In this way any deficiencies in the various components of the control system can be discovered and corrected. Complex guidance systems present a major challenge with respect to reliability and long life. Passive attitude-control systems are preferred because of their simplicity. However, in many cases performance requirements dictate direct and immediate control in all three modes of motion or require successive positioning in precise fashion.

For example, the OSO spacecraft must be capable of being pointed in a given direction with an accuracy of one minute of arc; for the OAO satellite the requirement is measured in seconds of arc. In such cases, complex command and control systems are required and these systems, therefore, are of vital concern in determining satellite reliability and performance. The best approach to an answer lies in the long-life guidance and control tests carried out on the ground.

Of equal importance, however, are diagnostic instrumentation and telemetry during the actual space flight, because if reliability and lifetime are to be improved it is necessary to know exactly why past satellites have failed. For this reason some weight and power must be allocated for diagnostic instrumentation which will continuously monitor the performance of the spacecraft, its circuitry, temperature, voltages and currents, and general performance. Thus, in the actual space environment the design and performance of the spacecraft can be monitored and analyzed, and corrective modifications can be made before future launchings.

(Jo. D. N.; R. J. Gu.)

IV. SPACE SCIENCE: PHYSICAL SCIENCES

Science is the expression of man's desire to explore and understand his natural environment. Space science is the extension of that exploration to those new regions of space and to those new phenomena which have become accessible to man as a result of the development of sounding rockets, satellites and deep-space probes. Before this, man was limited in his explorations to the Earth and its atmosphere up to an altitude of about 40 km. He was limited to the study of the natural phenomena which either occurred in this region of space or which emitted electromagnetic or particulate radiation which could penetrate the Earth's atmosphere to this region. He could observe the stars and galaxies in those colours of light which were not absorbed by the atmosphere, and could only speculate about the appearance of the planets and the stars in the ultraviolet and infrared light which is absorbed by the atmosphere. The development of the sounding rocket, the satellite, and the deep-space probe enormously increased the region of space which man can explore and the phenomena he can observe.

In order to understand the factors that must be taken into account in space science and to provide a proper perspective for this article it is necessary to remember that the Earth is immersed in the "atmosphere" of a small star, the Sun, and that the Sun controls the properties of the space occupied by the planets and provides the energy for the processes which take place on the Earth and other planets.

A. Solar Phenomena

The physical properties of the Sun are given in the article SUN. This section will cover primarily those solar phenomena of importance to space science or those which can only be studied by space techniques.

The Sun emits electromagnetic radiation in all wavelengths, from gamma rays to long wavelength radio waves. It also emits charged particles—protons, alpha particles, the positively charged nuclei of heavier atoms, and presumably electrons, although these have not yet been detected. The total power radiated by the Sun, 3.8×10^{33} ergs per second, is nearly constant, varying by less than 1%. However, certain regions of the electromagnetic spectrum, as well as the energies and intensities of the charged particles, are highly variable, both in time and in the location on the Sun from which they are emitted.

Fig. 12 is a graph of the amount of energy that the Sun radiates at each wavelength. The Sun radiates 99% of its energy in wavelengths between 3000 and 40,000 Å. The atmosphere is transparent to this portion of the solar spectrum (with the exceptions of the various absorption bands at 6884, 7621, 9419, 11,350, 14,000 and 18,000 Å shown cross-hatched in fig. 12) and consequently it has been studied extensively at ground-based observatories. The spectral distribution in this portion of the spectrum is similar to that of a 6,000° K. black body, and the radiation comes almost entirely from the photosphere of the Sun. This region of the solar spectrum is of importance to space science because it is primarily responsible for the temperature of objects in space. The solar energy incident on a planet determines the temperature of the planet. Mercury, being closest to the Sun, has a maximum temperature of about 410° C. (770° F.) whereas Jupiter, which is 5 astronomical units from the Sun, has a temperature of −138° C. (−216° F.). As a spacecraft moves closer to the Sun, more solar energy falls on it and its temperature rises.

The shorter wavelengths, below 2900 Å, which are absorbed by the atmosphere can only be studied with instruments on sounding rockets and satellites. Although the amount of energy involved is small, it is an interesting and important region of the solar spectrum. Below 2000 Å the character of the spectral-irradiance curve changes. It is no longer similar to that from a 6,000° K. black body; instead, there is a continuum similar to that of a 4,000° K. black body with a number of very intense emission lines. The intensity of these lines varies with solar activity. The radiation in this part of the spectrum comes not from the photosphere but from the chromosphere and corona of the Sun. Fig. 13 is an enlargement of that portion of the spectral-irradiance curve from 0 to 2000 Å, showing the more important emission lines and the continuum.

The region from about 1000 to 2000 Å is sometimes referred to as the vacuum ultraviolet, the region from 100 to 1000 Å as the extreme ultraviolet (EUV) and the region below 100 Å as the X-ray portion of the spectrum.

The Lyman alpha line of hydrogen (1216 Å) is the most prominent emission line in this region of the spectrum. The first measurements of this line were made with sounding rockets in 1949, and its intensity was continuously monitored on the first Orbiting Solar observatory (OSO-1) in March, April and May, 1962. All of these measurements indicate that the intensity of 6×10^{-7} w. per square centimetre is very nearly constant over a solar cycle. The OSO-1 observations indicated a systematic variation of a few per cent correlated with the number of active regions on the visible disk of the Sun.

Systematic observations of the relative intensities of the 304 Å (HeII), 284 Å (FeXV) and the 335 Å (FeXVI) lines were also made on OSO-1. The intensities of these lines varied in a systematic way with sunspot number and with the flux of 2,800 Mc. radio noise from the Sun. The intensities of the iron lines increased by a much larger factor than the intensity of the helium line, the differences presumably arising from the fact that these lines are produced at different levels in the solar atmosphere.

The solar corona also emits X-rays in the 0–100 Å region. Fig. 14 shows the solar spectral irradiance in the region from 0 to 100 Å for the normal corona and during a solar flare. The spectral-irradiance curve of the normal corona has a shape similar to that of a black body at 500,000° K.; however, the total energy radiated in this region of the spectrum is many orders of magnitude below

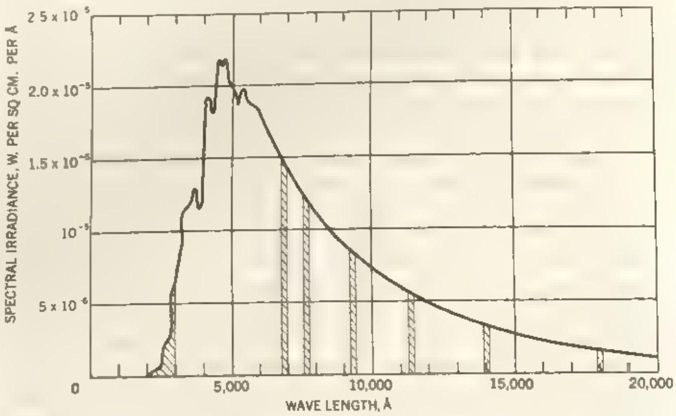

FIG. 12.—DISTRIBUTION OF ENERGY IN THE SOLAR RADIATION INCIDENT ON THE EARTH'S UPPER ATMOSPHERE. NARROW SHADED LINES ARE REGIONS OF STRONG ATMOSPHERIC ABSORPTION; SHADED AREA BELOW 3000 Å IS PORTION OF THE ULTRAVIOLET SPECTRUM ABSORBED BY THE ATMOSPHERE

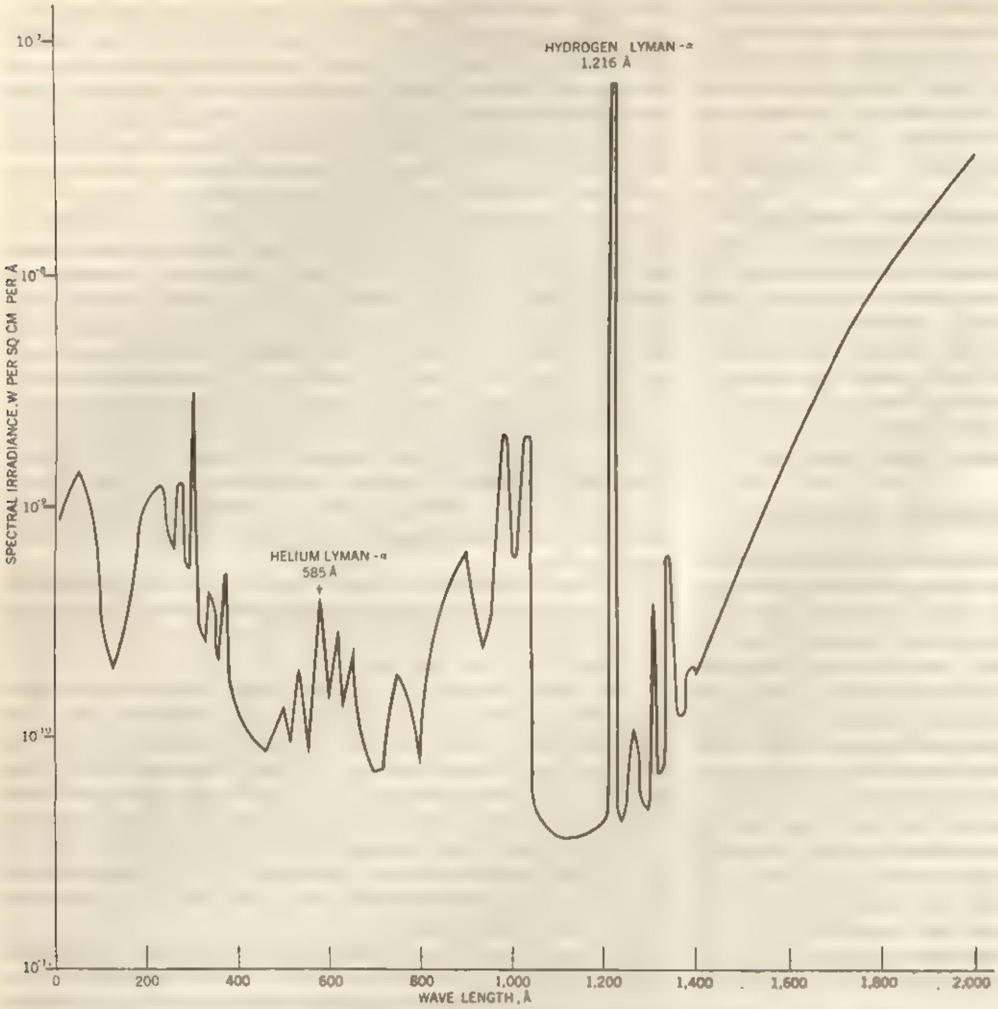

FIG. 13.—SOLAR ULTRAVIOLET SPECTRAL IRRADIANCE ABOVE THE EARTH'S ATMOSPHERE (*see* TEXT)

that which a body the size of the Sun would radiate at this temperature. At shorter wavelengths, 8–20 Å, the intensity varies markedly with solar activity. A typical value in this region is $0.1\text{–}2 \times 10^{-8}$ w. per square centimetre; for the region below 8 Å, 10^{-13} to 10^{-15} w. per square centimetre. During solar flares the shortest wavelength observed is normally about 1 Å although on a few occasions 0.1 Å X-rays have been observed, and on very rare occasions X-rays of 0.02 Å have been noted.

The values quoted for the fluxes of the various regions in the ultraviolet and X-ray spectrums are preliminary and in some cases are based on fleeting measurements made by sounding rockets. The absolute values will undoubtedly change somewhat as systematic, long-term measurements are made in orbiting observatories similar to OSO-1. The study of the spatial and temporal variations of this portion of the solar spectrum should contribute to the solutions to some of the puzzling problems of the chromosphere, the corona and solar flares discussed in the article SUN.

In addition to their importance in leading to an understanding of solar phenomena, the radiations emitted in the ultraviolet and X-ray region of the spectrum are equally important in the understanding of the physics of the upper atmosphere. Fig. 15 shows the altitudes at which the various portions of the spectrum are absorbed by the atmosphere. The properties of a particular altitude region of the atmosphere are determined by the radiation which is absorbed there. The interaction between solar radiation and the atmosphere will be discussed below under *Interplanetary Phenomena.*

The Sun also continuously emits a flux of low-energy charged particles generally referred to as the "solar wind." During large solar flares the Sun emits large numbers of high-energy protons or solar cosmic rays. The solar wind and solar cosmic rays are best observed in interplanetary space, and the solar wind in particular controls many of the properties of interplanetary space.

B. INTERPLANETARY PHENOMENA

Interplanetary space is defined as that region in the solar system whose properties are primarily determined by solar phenomena rather than by the presence of other bodies such as the planets. The Earth and its magnetic field, for instance, influence a region of space extending out about 70,000 km. on the daylight side of the Earth and about 300,000 km. on the night side. Outside this region the properties of space are determined by solar phenomena.

Four interplanetary phenomena will be discussed: the solar wind; the interplanetary magnetic field; solar and galactic cosmic rays; and micrometeorites. These phenomena determine the conditions in interplanetary space and vary appreciably with both time and position in space. In order to understand and describe their behaviour it is necessary to make measurements in interplanetary space.

The solar wind is a moving solar plasma (a plasma consists of a gas of electrically charged particles). Although the individual particles of a plasma are charged, the charges are both positive and negative, and the net charge on any finite volume of plasma is neutral. The solar plasma consists primarily of protons and, presumably, electrons, although the electrons have not yet been measured. The protons in this plasma have energies of about 1 Kev (thousand electron volts), which corresponds to a velocity of about 500 km. per second. Occasionally there is a period of activity on the Sun followed by changes in the behaviour of the solar wind. The number of the particles increases (for example, from less than one per cubic centimetre to more than ten) and their velocities also increase.

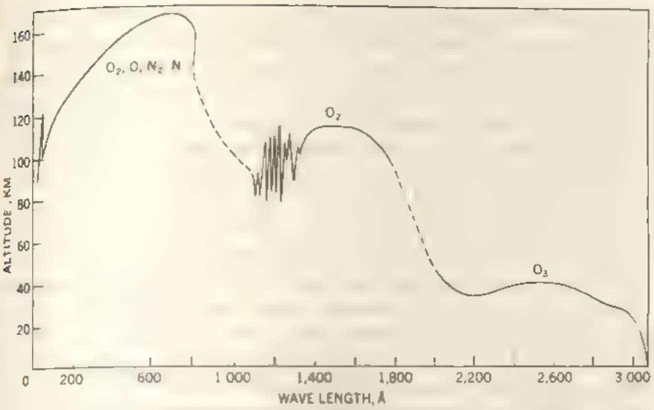
FIG. 14.—SOLAR X-RAY SPECTRAL IRRADIANCE ABOVE THE EARTH'S ATMOSPHERE (*see* TEXT)



FROM J. A. RATCLIFFE, "PHYSICS OF THE UPPER ATMOSPHERE"

FIG. 15.—PENETRATION OF SOLAR ULTRAVIOLET RADIATION INTO THE ATMOSPHERE. ABSORPTION ABOVE 2000 Å IS DUE PRINCIPALLY TO OZONE. BETWEEN 850 AND 2000 Å TO MOLECULAR OXYGEN AND BELOW 850 Å TO ALL CONSTITUENTS

The interplanetary magnetic field has a value of about 5×10^{-15} gauss. The direction of the field lies approximately in the plane of the ecliptic and at an angle of 40° to 50° with the Earth-Sun line. The magnetic field is carried outward from the Sun by the solar wind; hence, it fluctuates with solar activity. Although the field is very weak, it influences the trajectories of cosmic rays since it exerts a continuous force on any moving charged particle.

Galactic cosmic rays are thought to originate outside the solar system. Their intensity shows only a very small variation with solar activity and does not vary with direction. Their properties are discussed in detail in the article COSMIC RAYS. After a major solar flare the intensity of protons in the energy range from about 1 to several hundred Mev (million electron volts) increases by several orders of magnitude in the first few hours and then gradually returns to normal over a period of several days. During the first hour after a flare, while the intensity is increasing, the number of particles observed depends upon the direction of observation. It must also depend upon the position of observation in space, although no direct observation of such a variation has been made. The protons responsible for the increase in intensity are called solar cosmic rays. Except for their large variation in intensity and position they are identical with galactic cosmic rays. In addition to protons there are the positively charged nuclei of heavier atoms—helium, nitrogen, oxygen, and so on up the atomic scale. The relative abundances of these nuclei in the solar cosmic rays differ from those in the galactic cosmic rays and reflect the relative abundances of the elements in the Sun.

About two particles will strike a sphere of 1 sq.cm. cross-sectional area in 1 sec. from the normal galactic cosmic-ray flux. About 100,000 particles will strike a similar sphere in 1 sec. at the peak of a major solar flare.

Meteoroids are a class of astronomical objects which travel in eccentric orbits about the Sun. A meteoroid may strike the Earth's atmosphere and produce an observable effect called a meteor or "shooting star." The solid body which constitutes a meteoroid is called a meteorite and may vary in mass from 10^{-14} g. to several thousand kilograms. The very light meteorites, with mass of less than about 10^{-6} g., are called micrometeorites or "cosmic dust" and appear to be concentrated in the vicinity of planets. Measurements made by Pioneer 1 and Mariner 2, when compared with measurements made by satellites in the vicinity of the Earth, showed that the flux of dust at great distances from the Earth was almost 1,000 times smaller. The material in space is dominated by particles with a mass of about 10^{-9} g. About one particle of mass 10^{-10} g. strikes an area of 1 sq.m. in 1 sec. near the Earth. The integrated accretion rate over the entire surface of the Earth is about 10,000 tons per day.

C. THE EARTH

The Earth, of course, is the planet which has been studied most extensively. It is convenient to divide material in the realm of space science under four major headings: Geodesy, the study of the solid earth; the Upper Atmosphere; the Ionosphere; and the Magnetosphere.

1. Geodesy.—A satellite is a powerful tool for studying the gravitational field of the Earth and for locating points on the surface of the Earth. The position of a satellite in orbit can be determined within limits of about 10 or 20 m. By photographing a passive satellite or a satellite carrying a flashing light it is possible to determine its location relative to the fixed stars. Then, by determining the orbit precisely, studying variations in the orbit and correcting for those variations resulting from atmospheric drag and solar radiation pressure, it is possible to determine the gravitational potential and the exact shape of the Earth. From a knowledge of the gravitational potential it is possible to determine the variation of density within the Earth and to draw some inferences about the internal strength of the Earth.

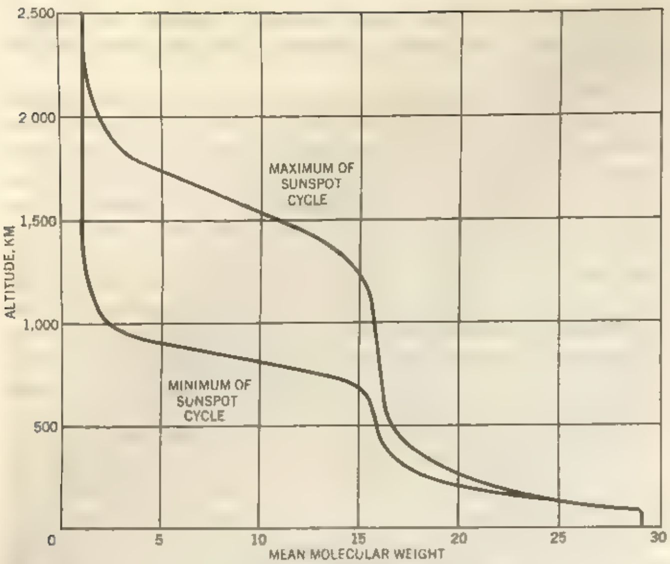
Simultaneous observations of a satellite can be used to determine precisely the relative locations of the observing stations on the surface of the earth. In this way triangulation measurements can be extended over great distances. (*See* also GEODESY.)

2. Upper Atmosphere.—As altitude increases, the first significant departure from the sea-level composition of the atmosphere occurs at about 30 km., where significant amounts of ozone (O_3) are observed. The upper atmosphere will be considered here as beginning at this altitude and extending up to about 200 km. Above this point, the properties of the atmosphere are determined by ions and free electrons and will be discussed in the section entitled *Ionosphere*. The upper atmosphere is studied primarily with sounding rockets; balloons are not feasible above 40 km. and satellites cannot be flown below about 200 km.

In order to describe and understand the atmosphere at a particular point, it is necessary to know its composition, temperature, pressure and density. All of these quantities vary with altitude and latitude, the time of day, the season and the solar cycle. An official publication, *A United States Standard Atmosphere*, gives these quantities as a function of altitude for an idealized middle-latitude atmosphere averaged over the yearly and solar-cycle variations.

The variation in temperature with altitude is largely controlled by the absorption of solar radiation. The rapid increase in temperature starting at about 100 km. and extending to about 300 km. marks the region in which ultraviolet radiation is absorbed. No temperature increase is noted above about 300 km. because no large amount of energy is absorbed in this region. Fig. 15 is a plot of the altitude at which about $\frac{2}{3}$ of the photons of a particular wavelength have been absorbed. The longer wavelengths (1000 to 2000 Å) are absorbed below about 50 km. by the ozone in the Earth's atmosphere. The wavelengths between 1000 and 2000 Å are absorbed by the oxygen in the atmosphere in the region between 50 and 150 km. The extreme ultraviolet radiation (500 to 1000 Å) is absorbed in the region between about 140 and 160 km.

Solar radiation is absorbed in the atmosphere by means of several processes, the two most important of which are photoionization and dissociation. In photoionization a neutral atom or molecule absorbs a photon and emits an electron, thereby forming an electron-ion pair. The electron will have an energy determined by the amount of energy required to liberate it from the atom and the amount of photon energy absorbed. In general, the electron will be emitted with an energy greater than the thermal energy of the ambient neutral particles. The electron then loses this energy by one of three processes: (1) inelastic collision with neutral particles; (2) elastic collision with ambient electrons; or (3) elastic collision with neutral particles and ions. The electron may remain a free electron or it may attach itself to a neutral molecule, thereby forming a negative ion. At altitudes below 60 km. electrons rapidly attach themselves to air molecules to form negative ions, the primary effect being an increase in conductivity of the air. At altitudes above 60 km. during the day, the density of the air is so low that the probability of attachment is small; the rate of production of electrons is high and thus there are an appreciable number of free electrons. At night the production



REPRINTED FROM "SATELLITE ENVIRONMENT HANDBOOK," ED BY FRANCIS S. JOHNSON, WITH THE PERMISSION OF THE PUBLISHERS, STANFORD UNIVERSITY PRESS. © 1961 BY LOCKHEED AIRCRAFT CORPORATION

FIG. 16.—VARIATION OF MEAN MOLECULAR WEIGHT OF THE ATMOSPHERE WITH ALTITUDE, SHOWING VALUES AT THE TWO EXTREMES OF THE SUNSPOT CYCLE

of electrons is very low, and those that are produced attach themselves to molecules, forming negative ions. Above 120 km. the density is so low that the electrons produced during the day remain free electrons during the night.

In the second major process, dissociation, a neutral molecule absorbs a photon and separates into two atoms. An example of this is the dissociation of the O_2 molecule into atomic oxygen. At very low altitudes, around 30 km., the neutral atoms of oxygen attach themselves to an O_2 molecule forming ozone, O_3. At higher altitudes, above 90 km., the density is low enough so that the probability of attachment to an O_2 molecule is small compared to the rate of dissociation and there is a large amount of atomic oxygen. The net effect is that there is a variation of the mean molecular weight of air with altitude. Fig. 16 shows the mean molecular weight for the two extremes of the solar cycle. At low altitudes, below about 90 km., the atmosphere has a mean molecular weight corresponding to the normal proportions of molecular oxygen and nitrogen. From 90 km. upward, the mean molecular weight drops rapidly as the oxygen molecules dissociate. The sharp drop in the mean molecular weight at 800 km. at solar minimum and 1,600 km. at solar maximum is due to the presence of the lighter constituents in the atmosphere. In this region the atmosphere is in diffusive equilibrium; therefore, the lighter components tend to separate out and become the dominant constituents at higher altitudes. Measurements on Explorer 8 showed that there is a large amount of helium ions present at about 1,600 km. At the very high altitudes, above 2,500 km., the mean molecular weight corresponds to that of atomic hydrogen.

3. Ionosphere.—One of the major energy-absorption processes in the atmosphere is the production of electron-ion pairs. At altitudes below about 90 km. electrons freed by this process are promptly attached to another molecule, forming a negative ion. Above 90 km. the electrons persist for a considerable length of time: in the regions around 200 km. the high concentrations of electrons persist even through the night. The ionosphere was one of the first regions of the upper atmosphere to be studied, because it reflects low-frequency radio waves that can be produced and detected with elementary equipment. A radio wave propagating vertically from the surface of the earth will be returned from a level in the atmosphere where the electron density and the frequency of the radio wave are related by the formula $N_e = 1.24 \times 10^4 f^2$ electrons per cubic centimetre, where f is the frequency in megacycles per second.

Experimentally it is found that the electron density increases with altitude up to about 350 km. Therefore, the higher the frequency used to probe the ionosphere, the higher the altitude from which the signal is returned. The ionosphere has been studied by sending a variable-frequency radio signal vertically upward and measuring the length of time required for the echo to return. This time is then a measure of the altitude at which the wave is reflected. At altitudes above about 300 km. and a frequency above 10 Mc. no echo is returned. At higher frequencies the wave is propagated upward; that is, the ionosphere becomes "transparent."

During the early studies of the ionosphere it was observed that as the probing frequency was increased it would be reflected at a particular level up to a certain limit; then the altitude of reflection would change discontinuously to a higher level, where a wave of higher frequency would be reflected. Thus, it was thought that there were distinct layers, each of higher electron density than the one below. These observations led to the characterization of certain distinct ionospheric layers or regions, the so-called D, E, F_1 and F_2 regions. However, this concept of sharp layers of ionization with little or no free electrons in the intervening regions proved to be wrong as shown in fig. 17. The regions or layers are really locations where the electron concentration reaches a peak, remains relatively constant for some distance, and then again increases.

The D Region.—The D region extends from 60 km. to about 90 km. Photoionization is produced by the Lyman alpha radiation of hydrogen and the primary ions formed are NO^+. Fig. 15 shows that there is a "window" at the frequency of the Lyman alpha line which makes it possible for this radiation to penetrate to the 60 km. altitude. In addition to the normal D region ionization produced in this way, high-energy solar X-rays emitted at times of solar flares can increase the electron concentration in the D region, and can extend appreciably downward the lowest altitude levels of ionization. Also, protons from solar flares can cause an enhancement of the electron concentrations over the polar regions of the Earth. When such an event as this takes place the increased ionization in the D region completely blacks out radio transmission. The increased ionization is produced by protons in the energy range from a few Mev up to several hundred Mev.

The E Region.—The altitude range from about 90 to 140 km. is designated the E region. It has been established that the "soft" solar X-rays are responsible for the photoionization which occurs in this range. The dominant ionic species in this region are O_2^+ and NO^+. The electron density in the E region is of the order of 10^5 electrons per cubic centimetre at noon during sunspot minimum and is increased by about 50% during sunspot maximum. Electron concentration is highest near local noon and falls off roughly symmetrically with time on either side of noon.

FIG. 17.—VARIATION OF ELECTRON DENSITY WITH ALTITUDE, SHOWN AT THE TWO EXTREMES OF THE SUNSPOT CYCLE

The F_1 Region.—There is no clear resolution between the F_1 region and the E and F_2 regions. The F_1 region is generally and rather arbitrarily defined as the altitude range from 140 to 200 km. The helium 304 line in the solar spectrum is responsible for the photoionization in this region. The photons of the helium 304 line have an energy of 41 electron volts. The energy required to free an electron is of the order of 13 electron volts, and therefore the electrons released in this region have a high energy and share their energy, through the mechanism of elastic collision, with the ambient electrons rather than with the ambient ions. Therefore, the electron temperature is several hundred degrees higher than the ion temperature during the daytime. Electron density in this region is of the order of 5×10^5 electrons per cubic centimetre at noon during sunspot minimum and 2×10^6 electrons per cubic centimetre during sunspot maximum. This region is not usually detected at night, when the electron density falls below 10^4 electrons per cubic centimetre.

The F_2 Region.—The F_2 region is not too well understood. It is thought that the helium 304 line from the Sun is also responsible for ionization there. The reason a second ionization peak is formed in this region is that the recombination rate decreases with altitude more rapidly than does the ionization rate, so that larger ion concentrations occur at higher altitudes.

Above the region of the second peak the electron concentration decreases as shown in fig. 17. The ionosphere in this region is studied by instruments carried on satellites, the first direct measurements being made by the early Sputniks. Alouette 1, a Canadian satellite, carried a swept-frequency "topside" sounder, an instrument similar to the conventional Ionosonde used on the ground. This satellite transmitted a radio signal in the 1–30 Mc. range which was reflected at a depth in the ionosphere given by the formula quoted earlier. In this case, since the transmitter was above the ionosphere, the higher the frequency of the transmitted signal the deeper it penetrated, until finally, at a certain critical frequency, it passed completely through the ionosphere and was reflected from the ground.

4. Magnetosphere.—The magnetosphere is defined as the region of space surrounding the Earth, influenced by the Earth's magnetic field, which begins at an altitude of about 400 km. and extends to about 10 Earth radii (64,000 km.) on the sunlit side of the Earth and to perhaps 40 Earth radii (256,000 km.) on the dark side. It is the region in space in which charged particles oscillating from the northern to the southern hemisphere have a lifetime that is long compared to the time required for a single oscillation. It extends out to a boundary which is sharp and well defined but whose location in space varies with solar activity and with the angle to the Earth-Sun line.

At the boundary the magnetic field changes direction sharply and decreases in strength. The intensity of the trapped radiation also decreases sharply. The transition region or boundary is only about 70 km. thick. Inside the boundary the magnetic field agrees with that predicted for a dipole magnetic field. Outside, the field is turbulent for a distance of several Earth radii until the conditions of interplanetary space are reached.

A charged particle moving in a magnetic field experiences a force at right angles to its direction of motion and to the magnetic field. As a result of this force the particle will spiral along a magnetic line of force. In a uniform magnetic field the particle would maintain a constant velocity and a constant "pitch angle" between its velocity vector and the magnetic field. If, however, it is in a region in which the strength of the field is changing, the pitch angle and the size of the spiral will change.

It is believed that the protons in the inner region arise from the decay of neutrons produced by the interaction of solar and galactic cosmic rays with air nuclei.

D. The Moon and Planets

The discussions in the articles Moon and Planets are based for the most part upon data from ground observations and theoretical analyses. The program of systematic exploration of the Moon and planets with unmanned and manned spacecraft did not begin until the 1960s. Soviet scientists measured the strength of the lunar magnetic field at the Moon's surface with Luna 2 and photographs of the far side of the Moon were obtained with Luna 3 (1959) and Zond 3 (1965). Ranger 7 in July 1964, together with Ranger 8 in Feb. 1965 and Ranger 9 in March 1965, provided more than 15,000 high-resolution photographs of the lunar surface. These photographs showed the lunar surface in the *maria* to be peppered with craters of various sizes and to have a smooth undulating contour. In 1966 the Soviet Luna 9 and the U.S. Surveyor 1 spacecraft "soft landed" on the Moon and provided close-up photographs of the lunar surface. The Surveyor 1 pictures showed the surface to be composed of granular material that ranged widely in size; coarse blocks of rock and smaller fragments contrast with fine particles too small to be resolved by a picture resolution of ½ mm.

The first measurements in the vicinity of a planet were made by Mariner 2, which passed Venus at a distance of 34,760 km. Magnetometers and radiation detectors on board the spacecraft showed no change in the magnetic field and no increase in the radiation level. This implies that Venus has no radiation belt, at least none extending out to 35,000 km., and that any field that it may have does not exceed the interplanetary magnetic field at that altitude. Two experiments to measure the planet's temperature gave a surface temperature of about 427° C. (801° F.).

In July 1965 Mariner 4 passed Mars at a distance of 9,868 km. (6,118 mi.) and transmitted 22 photographs (19 of them useful) of about 1% of the planet's surface to the Earth. The pictures revealed a barren, crater-pocked surface that resembled that of the Moon. Mariner 4 also discovered that the Martian atmosphere was thinner than had been expected, and found no evidence of a magnetic field or of a surrounding belt of radiation.

E. Astronomical Phenomena

The atmosphere absorbs the ultraviolet light from the stars just as it does from the Sun. However, while the Sun emits the bulk of its energy in the visible region of the spectrum, there are stars which emit most of their energy in the ultraviolet portion. In addition to absorbing a major portion of the electromagnetic spectrum, the atmosphere also distorts and scatters a large fraction of the light. For these reasons extremely accurate pointing of large telescopes for long periods of time is required.

The ultraviolet spectra of stars have been measured with instruments on sounding rockets. Preliminary results indicate that intensity in the ultraviolet is below that which would be predicted from our present understanding of stellar processes.

Explorer 11 carried an experiment to measure the flux of high-energy gamma rays. This experiment gave a very low flux of gamma rays and gave no evidence of any discrete sources.

Experiments with sounding rockets have given evidence for discrete sources of X-rays. If subsequent experiments confirm these early results the measurements of the X-ray flux will help to understand stellar processes. (J. E. N.)

V. SPACE SCIENCE: LIFE SCIENCES

Bioastronautics, a term used to describe the space life sciences, includes acquisition of knowledge in space biology and application of this knowledge to manned space exploration.

Of the technologies which transform basic scientific knowledge into practical use, biologistics is perhaps the broadest. It includes all knowledge, techniques, equipment and supplies required for life support and crew protection, such as environmental control systems, space suits, food, water and waste management devices. This article will treat bioastronautics in two broad categories. The first, concerned with the search for fundamental scientific knowledge, will be called space biology. The second will describe applied bioastronautics in terms of major unsolved technical problems and the special knowledge, procedures and equipment needed to support astronauts in space.

A. Origin of Bioastronautics

Although men have for many centuries speculated on the probable biological effects of the space environment, the first serious investigations of space hazards resulted from a near-disaster in

1862 when two British balloonists, having reached an altitude of about 29,000 ft., narrowly escaped death from acute oxygen deprivation or hypoxia. The French physiologist Paul Bert, stimulated by reports of this experience, began studying respiratory physiology and the biological effects of barometric pressure.

Bert had the first low-pressure chamber suitable for studies on human subjects. His classic observations formed the basis for aviation medicine, a biomedical specialty which developed slowly until the fourth and fifth decades of the 20th century, when revolutionary advances in aeronautics resulted in a broad and vigorous program of research. One of the first units devoted to biomedical research exclusively in space problems was the department of space medicine, established at the U.S. air force School of Aviation Medicine in 1949 by Harry G. Armstrong, an aviation medicine research pioneer. The rapidly growing body of knowledge in aviation medicine, together with technical developments in aircrew protective equipment, by the time of Sputnik 1 and Sputnik 2 formed the scientific and technological base for bioastronautics in the space age.

FIG. 18.—BIOLOGICAL EFFECTS OF THE SPACE ENVIRONMENT, SHOWING INTERRELATIONSHIP OF THE VARIOUS EFFECTS (*see* TEXT AND TABLE VI)

B. Space Biology

1. Environmental Biology.—Underlying the many problems in the adaptation of man to space flight are fundamental considerations of the relationship between any living organism and its environment. In a broad sense, the definition of life and its fundamental characteristics are established by this relationship.

Space flight offers an unprecedented opportunity for studying the influence of environment on life characteristics and processes; namely, to determine what effects may proceed from the absence of the normal gravitational force and rotation of the Earth and the presence of ionizing radiation in levels much greater than those on Earth. The absence of the normal gravitational force to which Earth organisms are adapted through evolution may be expected to have effects on the systems in Table VI, with interactions as shown in fig. 18.

Table VI.—*Biological Processes for Study in Space*

A. The role of gravity in:
- (1) Plant morphogenesis
- (2) Animal morphogenesis
- (3) General physiology of cells:
  - (a) Cell nutrition
  - (b) Protein and nucleic acid syntheses

B. Effects of weightlessness (lack of gravitational stimulus) on:
- (1) Animal co-ordinative processes (*i.e.*, orienting reflexes)
- (2) Plant and animal fluid transport (*i.e.*, blood and lymph flow)
- (3) Mammalian physiological processes (*i.e.*, homeostatic mechanisms)

C. Space radiation effects:
- (1) Biological effectiveness of particles having energy not available from accelerators
- (2) Possible synergism between ionizing radiation and other factors in orbital flight (*i.e.*, weightlessness, altered rhythmic processes)

D. Effects of removal from the Earth's rotation on diurnal cycles, time-dependent phenomena, growth of spiral structures

Experimental systems were under development in the 1960s in the biosatellite project of NASA; it was planned to put recoverable spacecraft in orbit for periods of up to 30 days, carrying a wide range of biological experiments involving organisms from bacteria to subhuman primates, to seek answers to the problems outlined in Table VI and fig. 18.

2. Exobiology.—Exobiology is the science of extraterrestrial life. The most revolutionary finding anticipated in the exploration of space would be the discovery of extraterrestrial life or evidence of its preexistence. Aside from its popular impact, this discovery and subsequent investigation would have deep bearing on such topics as the origin of life, organic evolution and even the evolution of the universe.

One of the most widely accepted characteristics of life is the ability to derive energy and matter from the environment and to utilize them for growth and reproduction. Chemical studies on the synthesis of carbon compounds associated with terrestrial life suggest that the synthesis of such substances must occur with great frequency in the universe; therefore, the probability of multiple formation of carbon-based life in the universe is very high. (The probability that life may be derived from other chemical systems is not ruled out, but it is much more difficult to evaluate.) Knowledge of terrestrial evolution leads to the fruitful proposition that life, once it appeared, would evolve into a wide variety of forms to exploit the environment. This proposition raises the distinct possibility of sentient, communicating life forms elsewhere in the universe.

Within the narrow confines of the solar system, however, the most probable forms of life outside the earth are microorganisms (the extant theories of evolution all postulate such forms as a starting point of life). Therefore, exobiology is primarily concerned with the recognition of carbon-based microorganisms on planets of the solar system. Of these planets, Mercury may have too high a temperature for ordinary organic syntheses to occur. Venus, from data derived from Mariner 2, appears to be too hot for conventional biochemistry based on an aqueous medium. Jupiter is too remote for study in the present state of technology.

Including the data obtained by Mariner 4, Mars is still by far the most attractive prospect for the presence of life processes. The seasonal appearance of dark areas associated with the apparent thaw of polar caps may mean that some life forms, perhaps vegetation, revive as warmth and water become seasonally available.

The principal U.S. programs directed toward the investigation of life on Mars are the NASA Mariner and Voyager projects. These include "fly-by" and orbiter missions to gather and record data from electromagnetic radiation either emitted or reflected from the planet by means of spectroscopic analysis, television photography, thermal mapping, etc. Landing capsules were planned that would detect life by identifying some of its most universal characteristics (Table VII); physical-chemical methods were proposed to identify organic compounds. A typical life detection device is illustrated in fig. 19.

Table VII.—*Characteristics or Techniques Useful in the Search for Extraterrestrial Life*

1. Biologically significant elements and diatomic combinations
2. Carbon compounds; organic compounds; optically active compounds
3. Water in liquid form in sufficient amount to permit activity; theoretical substitutes for water
4. Temperatures less than 100° C.
5. Proteins, nucleic acids and amino acids
6. Special staining or dye reactions typical of macromolecules
7. Growth and metabolism
8. Carbon-dioxide assimilation (photosynthetic and autotrophic bacteria)
9. Enzymes or enzyme activity
10. Structure and organization typical of living systems
11. Gross observations by means of near-scan, high-resolution television
12. Bioelectrical phenomena

C. Problems of Man in Space

1. Biological Space.—A general scientific definition of space appears in the introduction to this article. In bioastronautics, the definition of space is necessarily associated with its relationship to man. For instance, the unadapted human being becomes partially incapacitated from hypoxia when exposed to altitudes above 10,000 ft. Equipped with pressure-breathing oxygen apparatus,

an aviator can function effectively up to altitudes of about 45,000 ft. However, at any altitude above 18,000 to 20,000 ft., and particularly above 30,000 ft., there is some risk of an attack of the "bends," or decompression sickness. At altitudes above 45,000 ft. an artificial pressure environment is essential to prevent severe decompression effects and to permit adequate oxygenation.

Where space begins is not determinable from a bioastronautics point of view. From a physiological standpoint, space equivalence in terms of atmospheric pressure may be said to begin at about 65,000 ft. The radiobiologist interested in manned space flight recognizes the vicinity of 90,000 ft. as an altitude at which space radiation begins to be significant.

2. Hazards and Stresses of Space Flight.—The environmental hazards of manned space flight include weightlessness, penetrating radiations, "hard" vacuum, temperature extremes, meteorites, and intense, though transient, accelerative and vibratory forces of launch, orbital injection, in-flight maneuvers, reentry and landing. Other factors which may pose problems of safety or effective performance for space travelers include reduced magnetic fields; empty visual fields; unattenuated solar radiation in the ultraviolet, visible and thermal zones; the absence of the customary terrestrial day-night cycle; and the vastness, desolation and silence of space.

Weightlessness.—The accumulating human experience in the "zero-g" weightless state typical of orbital space flight will show whether or not exposure to this state, prolonged for many days, weeks or months, will produce detrimental biological effects. The Mercury and Vostok flights showed that astronauts were able to carry on normally and efficiently as spacecraft operators. Some evidence has accumulated of adverse effects on arterial blood pressure, seen immediately after landing from orbital flights. A very practical question concerns the possibility that prolonged exposure to weightlessness may so de-condition the astronaut that his cardiovascular system may not be capable of compensating for the increased accelerative stresses of reentry, nor for the circulatory demands of standing or moving about during the first few hours or days back on Earth. Moreover, there is lively scientific interest in the possible influence of prolonged weightlessness on various metabolic and regulatory processes, particularly on calcium metabolism and the possibility of skeletal atrophy, kidney stone formation, and predilection for arterial blood clots as a result of elevated blood calcium levels. Similarly, the possible adverse effects on muscular size and strength must be elucidated. Since it is impossible to simulate prolonged weightlessness in Earth laboratories, the answers to numerous questions about its biological and behavioural effects must come from experience in actual space flight, whether from orbiting animal-carrying satellites or spacecraft with human crews.

FIG. 19.—RADIOISOTOPE BIOCHEMICAL PROBE KNOWN AS "GULLIVER." LIFE-DETECTION DEVICE IS 5½ INCHES IN DIAMETER AT THE BASE AND HAS THREE "STICKY STRINGS," FIRED IN DIFFERENT DIRECTIONS BY BULLETS, THEN REELED BACK, CARRYING SOIL PARTICLES AND MICROORGANISMS INTO A NUTRIENT BROTH. BACTERIA, IF PRESENT, WILL GROW IN BROTH, AND APPROPRIATE SIGNALS WILL BE SENT TO EARTH

Radiation.—It was estimated that the Apollo manned lunar landing and return mission could be accomplished without exposing the crew to radiation of more than 25 rad (radiation absorbed dose; *see* RADIOLOGY: *Therapeutic Radiology: Dosage*). This includes radiation from all sources—the artificial electron belt, the Van Allen Belt, galactic sources and high-magnitude solar flares. An emergency total dose of 150 rad is regarded as a maximum consistent with mission completion and minimum crew safety. This much radiation, however, if absorbed in as short a time as one hour, might produce some symptoms of acute radiation sickness, such as nausea and malaise; however, control of these symptoms with standard drugs is considered feasible.

Since knowledge of the biological effects of high-energy protons and other high-energy space radiations is insufficient to make precise estimates of the hazard to space travelers, laboratory proton accelerators are being used, in part, for proton biological effects studies. There is a modest hope that at least two types of radiation treatment may evolve to a practical state: antiradiation prophylactic drugs and the use, after radiation exposure, of autologous bone marrow.

More powerful space boosters, capable of orbiting large payloads, will allow for the inclusion in the spacecraft design of considerably more inert radiation shielding than can be carried in, for example, the Gemini spacecraft. In the mid-1960s there was optimism regarding the development and perfection of a magnetic means of deflecting charged, high-energy particles from spacecraft.

High-Intensity Light.—Visible solar radiation in space is so intense that, without protective filters in his glasses, helmet visor or spacecraft windows, the astronaut viewing the Sun directly could suffer temporary blindness or even permanent retinal burns. The form of objects viewed in such unscattered solar light may be difficult to discern accurately because of the high contrast between the illuminated and nonilluminated parts.

Ultraviolet Light.—Unattenuated solar ultraviolet light is another hazard to the space traveler. This is not a serious danger because the space suit will efficiently shield against ultraviolet radiation. There is some concern, however, about the deteriorating effects of ultraviolet radiation on materials used in the construction of spacecraft and space suits.

Temperature Extremes.—The range of temperatures to which an astronaut might be exposed is well illustrated by temperature estimates of the Moon's surface. On the dark side at lunar midnight, which is about 160 hr. after lunar sunset, the surface temperature drops to an estimated −150° C. (−238° F.). Conversely, at lunar midday, it would reach a scorching 180° C. (356° F.). Since these temperature extremes are well beyond the tolerance of an unprotected man, the lunar explorer and the astronaut operating in free space outside the spacecraft require insulated pressure suits with reflective outer layers and built-in, temperature-controlled ventilation.

The Vacuum of Space.—Interplanetary space is an extreme vacuum (with a pressure in the order of 10^{-14} mm. of mercury). Exposed to such a condition, the unprotected human being would have less than 15 sec. of consciousness before the onset of acute hypoxia and immediate, catastrophic decompression symptoms including bends, chokes, palsies and ebullism (the profuse evaporation or "boiling" of body fluids). To protect the astronaut against the vacuum of space, U.S. spacecraft are designed to contain a normal operating pressure of 5 p.s.i.a. (pounds per square inch, absolute) of 100% oxygen, and a minimum emergency pressure of 3.5 p.s.i.a. In addition, the astronaut wears a pressure suit which will maintain an internal pressure of 3.5 p.s.i.a. for as long as may be necessary to correct any environmental control system malfunction or to complete the mission and return to Earth.

Isolation and Sensory Deprivation.—Space flights subject the astronauts to varying degrees of physical and social isolation. Laboratory experiments, as well as the experiences of castaways and explorers, indicate that man, when deprived of the customary sights, sounds, smells, vibrations and thermal and kinesthetic sensations, as well as social interactions, may experience profound psychological disturbances to the point of severely impaired judgment and noneffectiveness. Studies and experience show that communication, as by radio, reduces somewhat the sense of isolation. Space missions with multiple crew members, good communications with Earth stations and demanding work schedules will greatly relieve the relative isolation and reduced level of sensory experience.

Empty Visual Fields.—The so-called empty visual field has been important in aviation because it causes problems of accommodation and visual effectiveness. It has been shown that in the presence of an empty visual field, such as a cloudless sky in broad daylight, subjects cannot relax their visual accommodation sufficiently to assure a visual focus at infinity. Instead, the subject experiences a temporary nearsightedness. This situation interferes radically with effective visual search for targets located at visual infinity. Whether or not this impairment will be important in space operations remains to be proved. It is probable that the stars, planets and Moon will afford some of the needed detail in the distant visual fields to permit accommodation of the eye.

Acceleration.—Throughout a typical space mission the astronaut is subjected to an acceleration environment that differs radically from the customary terrestrial situation. The principal features of this unusual experience are: the intense, short-duration, positive accelerations of the launch and staging phases; the long period of weightlessness in orbit; and the various accelerative forces of orbital maneuvers; all culminating in acute deceleration during retrofire, atmospheric reentry and the landing impact.

Aerospace medical research has determined that, with the subject semireclined and well supported, the predicted accelerations in all proposed manned flights are not only tolerable but compatible with an acceptable degree of mental and visual effectiveness and competence in using the fingers and hands for control manipulations. Atmospheric reentry of a Gemini-type spacecraft from a low Earth orbit, such as 120 mi., is marked by a period of decelerative force which lasts for several minutes and may reach as high as 8 to 10 g. Fig. 20 shows two reentry deceleration curves which have been proved by centrifuge testing to be within human tolerance when the subject is properly positioned and supported.

3. Biologistics.—This subject includes the characteristic problems that arise in designing and equipping manned spacecraft. Space crew requirements, as listed in Table VIII, form the basis for many aspects of spacecraft design and are essential specifications for biologistics. From these requirements are evolved the designs for environmental control systems to regulate cabin temperature, pressure, atmospheric composition and humidity; space suits; acceleration couches and restraining devices; food- and waste-handling equipment; and other equipment needed to sustain the space crew throughout the mission.

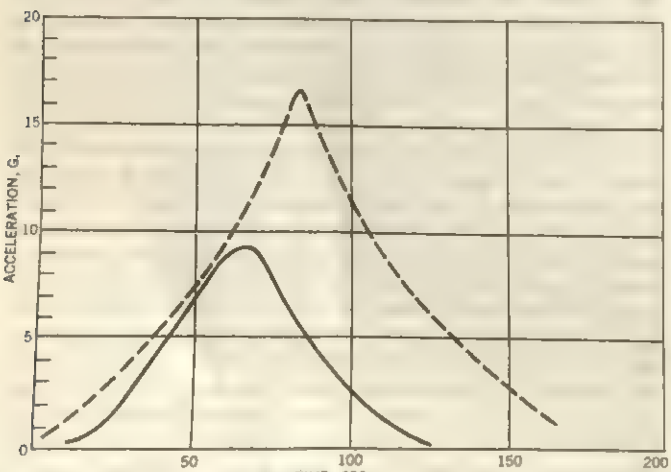

FIG. 20.—TWO EXPERIMENTAL REENTRY DECELERATION CURVES, SHOWING VALUES THAT ARE WITHIN RANGE OF HUMAN TOLERANCE

Manned space flights can be provided with oxygen, food and water for missions of six weeks or more. Partial recovery of water from human wastes and wash water, and regeneration of oxygen from carbon dioxide, would permit somewhat longer missions. However, for long-duration space flights of many weeks or months, in order to keep within the weight and space limitations imposed by the energy requirements for over-all mission completion, it will be necessary to eliminate all but an initial store of consumable supplies and to depend upon a closed ecological system for waste conversion and recovery of life-supporting essentials. In long-duration, earth-orbiting missions it might be feasible to resupply the spacecraft periodically by logistics vehicles. One of the most fascinating, if not the most difficult, technological challenges of the space age is the development of practical closed ecological system concepts in which essentially all waste products, both man- and machine-generated, could be converted for reuse. (O. E. Re.; J. M. Ta.)

TABLE VIII.—*Space Crew Requirements*

Area	Requirements	Item
Metabolic	Oxygen consumption	2.0 lb./man/day
	Carbon-dioxide output	2.3 lb./man/day
	Heat output	11,300 B.T.U./man/day
	Water consumption	6.0 lb./man/day
	Food consumption	2,800 kg.cal./man/day
Environmental	Cabin pressure	5 p.s.i.a. and 100% oxygen or 15 p.s.i.a. mixed oxygen-nitrogen
	Space suit pressure	3.5 p.s.i.a.
	Cabin temperature	75° F. ± 5° (rel. hum. 40%–70%)
	In-flight acceleration	(examples, "eyeballs in" or back to front) 10 g for 1.5 min., 9 g for 2 min., 7.5 g for 3 min.
	Noise levels	80 decibels over-all; 55 db in 600–4,800 cps range

VI. MANNED SPACE FLIGHT

1. Initial Programs.—A goal of both the U.S. and Soviet space programs was the achievement of manned orbital flight. Both nations based their projects on the use of existing ballistic-missile launch vehicles. Because the Soviet ballistic missile had been designed to carry a heavier warhead, their manned spacecraft could also be heavier than its U.S. counterpart; the U.S.S.R. Vostok spacecraft weighed approximately 10,400 lb., while the U.S. Mercury weighed about 3,000 lb.

Soviet Flights.—On April 12, 1961, Yuri Gagarin became the first man to orbit the Earth. In his spacecraft, Vostok 1 (East 1), he circled the Earth once, after a launching near Baikonour, U.S.S.R. On Aug. 6, 1961, Gherman Titov circled the Earth 17 times in Vostok 2, in a 25-hr. flight.

The duration of weightless flight was further extended in a "group flight" by Andrian G. Nikolayev and Pavel Popovich. Nikolayev was launched Aug. 11, 1962, and Popovich was injected into a nearly identical orbit one day later. Both remained in orbit until Aug. 15, Nikolayev completing 64 orbits and Popovich 48. At one point the craft came within 5 mi. of each other but were more than 1,000 mi. apart before reentry.

A second group flight took place in June 1963. On June 14 Valery Bykovsky was launched in Vostok 5. Two days later Valentina Tereshkova, the first woman cosmonaut, was launched in Vostok 6. Both spacecraft returned on June 19, Bykovsky completing 81 orbits and Miss Tereshkova completing 48. In neither group flight was there an attempt at rendezvous.

TABLE IX.—*Manned Space Flights*

Name	Nation	Pilot	Launch date	Weight (lb.)	Perigee/ Apogee (mi.)*	Number of orbits	Time (hr.:min.)
Vostok 1	U.S.S.R.	Yuri A. Gagarin	April 12, 1961	10,419	112/203	1	1:48

*Minimum perigee and maximum apogee, in statute miles. †Maximum altitude, statute miles (ballistic flight). ‡Range, statute miles.

United States Flights.—The first U.S. manned space flight took place on May 5, 1961, when Alan B. Shepard, Jr., flew a short-range ballistic trajectory in a Mercury spacecraft boosted by a Redstone launch vehicle. He reached an altitude of 116.5 mi., a speed of 5,100 m.p.h., and covered a distance of 300 mi. The period of weightless flight was about 5 min. On July 21, 1961, Virgil I. Grissom made a nearly identical flight.

The first U.S. orbital flight took place on Feb. 20, 1962, when John H. Glenn, Jr., completed three orbits in his Mercury spacecraft "Friendship 7." M. Scott Carpenter completed a similar flight on May 24, 1962, and Walter M. Schirra, Jr., made a six-orbit flight on Oct. 3, 1962. The last flight in the Mercury series took place on May 15–16, 1963, when L. Gordon Cooper, Jr., circled the Earth 22 times.

2. Gemini.—While the Mercury and Vostok programs demonstrated man's capabilities in space, their scope was too limited to permit the development of operational proficiency in manned space flight. In the United States the Gemini project was designed to continue where Mercury left off.

Objectives.—The Gemini project had two prime objectives: to extend the duration of flight to as long as two weeks, and to develop techniques for performing a rendezvous in space. The two-man Gemini spacecraft resembles the Mercury spacecraft in shape but is somewhat larger; it weighs more than twice as much as Mercury. The Gemini spacecraft is not fitted with the Mercury-type escape rocket; instead, ejection seats are used for emergencies. This is possible because the Gemini booster—the Titan II—uses storable hypergolic propellants which create a smaller explosion hazard than the liquid oxygen and kerosene used in the Atlas.

Rendezvous Maneuvers.—In a Gemini rendezvous mission, the "target" vehicle is placed into orbit first. The target can be an Agena stage or, alternatively, a passive "docking adapter," placed into orbit by an Atlas launch vehicle. (The target vehicle can also be another manned Gemini spacecraft.) Some time after being launched the target again passes over the launch site. For example, if the Agena's orbital period is exactly 90 min., then it will pass over the launch site 16 orbits or 24 hr. later, when the earth has completed exactly one rotation. If the Gemini spacecraft is then launched at the correct time, it could ideally be inserted into an orbit that is identical to that of the Agena, with the spacecraft and target flying close to each other. Under such ideal conditions, the pilots would then make small maneuvers, using their rocket "thrusters," to join the two craft.

For many practical reasons, these ideal conditions cannot be achieved in actual flights. First, it may be difficult to launch the spacecraft at precisely the right moment. A delay of one second allows the target vehicle to fly five miles beyond the rendezvous point. Second, the launch vehicle guidance systems, although extremely accurate, cannot insert the Gemini spacecraft into the exact same orbit as the Agena. (An error of $\frac{1}{10}$ of 1% in cutoff velocity would cause a height error of more than one mile, one-half revolution after insertion.) Under normal conditions, therefore, the moment of launch is extended to a "launch window" of several minutes duration. Catching up with the Agena and other orbit adjustments are accomplished during flight by using propulsion systems on the Gemini or Agena.

If the two craft are in the same orbital plane but are out of phase (*i.e.*, if they pass the same point at different times), the required corrections can be made with a minimal expenditure of fuel. In this case, one craft is placed into a more elongated orbit with a longer period; the other, in its original orbit with the shorter period, will then overtake the first. The orbit of the first is again shortened after the distance between the two craft has been decreased. These changes require relatively little propulsion.

If the two spacecraft are injected into different orbital planes, the corrective maneuver becomes more difficult. For a given plane change α, a velocity increase equal to $2V\sin\frac{\alpha}{2}$ is required, where V is satellite velocity. Thus, for a 5° plane change, a velocity increment of about 2,200 ft. per second would be required, while for a 60° change an increment equal to satellite velocity (about 25,500 ft. per second) is needed. Even with Agena propulsion, only minor plane changes are possible in Gemini.

A complete rendezvous maneuver, therefore, comprises the following: launch within a specified "window," plane change, phase change, rendezvous and docking.

Gemini Flights.—On March 23, 1965, astronauts Virgil ("Gus") Grissom and John W. Young made the first manned flight in a Gemini spacecraft, a three-orbit mission. The second manned Gemini flight, a four-day mission, took place in June 1965, with astronauts James A. McDivitt and Edward H. White II. White left the spacecraft for about 20 min. during the third orbit and maneuvered freely in space at the end of a 25-ft. tether.

FIG. 21.—MERCURY AND GEMINI (TWO-MAN) SPACECRAFT, SHOWING COMPARATIVE SIZES

In Aug. 1965 L. Gordon Cooper, Jr., and Charles Conrad, Jr., circled the Earth for eight days in the third manned Gemini flight.

Two major Gemini objectives, long-duration flight and rendezvous, were achieved in Dec. 1965. On Dec. 4, astronauts Frank Borman and James Lovell, Jr., began a flight that lasted more than 330 hr., just a few hours less than two weeks. On the eleventh day of the Borman/Lovell Gemini 7 mission, astronauts Walter M. Schirra, Jr., and Thomas Stafford started their Gemini 6 flight, which culminated in a rendezvous with Gemini 7. The spacecraft flew in close formation for many orbits, prior to the return to Earth by Gemini 6 on Dec. 16 and Gemini 7 on Dec. 18.

In March 1966 astronauts Neil Armstrong and David Scott performed a similar rendezvous but with an unmanned Agena. After rendezvous they "docked" with the Agena, firmly joining the two craft. A subsequent short circuit in one of the spacecraft systems forced an early termination of the flight. Nevertheless, the pilots flew a precise reentry, landing within sight of a recovery airplane.

Astronauts Thomas Stafford and Eugene Cernan flew the third Gemini rendezvous mission, Gemini 9, in June 1966. They gained operational proficiency in rendezvous by joining their target vehicle three separate times. Cernan left his spacecraft for more than two hours in an extended extravehicular activity.

In July 1966 Young and Michael Collins flew the complex Gemini 10 mission, which included rendezvous and docking with an Agena; use of Agena propulsion to fly to an altitude of 474 mi.; rendezvous with an Agena left in orbit during the Gemini 8 mission; and extravehicular activity to retrieve a micrometeorite crater collection experiment from the Gemini 8 Agena.

In Sept. 1966 Charles Conrad, Jr., and Richard F. Gordon, Jr., docked the Gemini 11 with an unmanned Agena on the first orbit. Using the power of the Agena, Gemini 11 ascended with it to an altitude of about 850 mi. While outside the spacecraft for about 45 min., Gordon joined the two craft with a tether. Conrad later used the tether to rotate the Gemini 11 around the Agena in a station-keeping exercise that produced artificial gravity. Astronauts James A. Lovell, Jr., and Edwin E. Aldrin flew the last manned Gemini mission, Gemini 12, in Nov. 1966. The flight included rendezvous, docking with an Agena, two extended periods of extravehicular activity, a tethered station-keeping period and a precise landing within 3.8 mi. of the planned landing point.

Gemini Experience.—The experience gained in Gemini included: 1,940 man-hours in space; long-duration flight; precision maneuvers, culminating in rendezvous on 10 occasions, using 7 different methods; station-keeping with and without a tether; 9 exercises in docking with another vehicle; 11 periods of extravehicular activity, totaling 12 hr. and 35 min.; a record altitude of 851 statute miles; and precision-controlled landings, within approximately 7 nautical miles of the aiming point on the last 7 flights. Also, the astronauts successfully performed 40 scientific, technological and medical experiments. The Gemini flights clearly demonstrated that man can easily adapt to the weightless space environment for periods of at least 14 days and then readapt to the gravitational environment of earth.

3. Voskhod and Soyuz.—The first Soviet multi-manned space flight took place on Oct. 12–13, 1964, when Voskhod 1 ("Sunrise 1") orbited the Earth 16 times. Piloted by Vladimir M. Komarov, the craft also carried Konstantin P. Feoktistov, an engineer-scientist, and Boris B. Yegorov, a physician. The crew wore standard clothing rather than pressure suits during this flight; a landing system comprising parachutes and braking rockets permitted the craft and its occupants to land on the ground. Voskhod 2, a two-man vehicle piloted by Pavel Belyayev, was launched on March 18, 1965. During this flight Alexei Leonov, co-pilot, left his spacecraft briefly, becoming the first man to float freely in space.

In April 1967 the U.S.S.R. launched Soyuz 1, described as the largest and most complex spacecraft yet to be flown. However, the pilot, Vladimir Komarov, apparently encountered difficulties early in the flight. During the 18th orbit he attempted to land the craft, but it became tangled in its parachute cords and crashed to earth in central Asia; Komarov was killed, becoming the first known space flier to die during a space flight.

4. Lunar Landing Program.—In May 1961 the U.S. announced plans to land a manned spacecraft on the Moon by the end of the 1960s. The name given to the program was Apollo.

Lunar Landing Techniques.—Several techniques for the lunar mission appeared to be feasible and were studied in detail. These included the "direct method," wherein a single giant launch vehicle (Nova) would launch a spacecraft toward the Moon. Near the Moon the spacecraft would be slowed down by its own propulsion system, called the lunar landing stage. Another propulsion system, the lunar takeoff stage, would launch the spacecraft from the Moon and send it on its return trajectory toward Earth.

A second proposal, called the "earth-orbit rendezvous" method, differed from the direct method in that two somewhat smaller launch vehicles (Saturn V) would separately transport two parts of the spacecraft (*i.e.*, the lunar landing stage as one part, and the lunar takeoff stage and spacecraft proper as the second part) into Earth orbit. There they would be joined and then propelled as a single craft toward the Moon.

A third method, called the "lunar orbit rendezvous" method, would employ a single Saturn V launch vehicle to send the three-man Apollo spacecraft, weighing 90,000 lb., on a trajectory toward the Moon. Approximately 2½ days later, as the craft approached the Moon, its own propulsion system would place it into an orbit around the Moon. In lunar orbit one element of the spacecraft, called the lunar module (LM), with two men aboard, would separate from the mother ship. The two men would then fly the LM toward the Moon, while the third man circled the Moon in the other section of the spacecraft, the "command mod-

ule." After executing a "soft" landing on the lunar surface, the two lunar explorers would make scientific observations and collect geological samples. After about one day, they would take off from the surface and fly toward a rendezvous with the command module in lunar orbit. After the rendezvous, spacecraft propulsion would eject the spacecraft from lunar orbit and send it back toward the Earth. Precise guidance and control on the return trip would allow the spacecraft to enter within the limits of a rather narrow "reentry corridor." This corridor, about 25 mi. high, is limited at the lower side by too thick an atmosphere, which would cause the craft to exceed acceptable deceleration limits, and at the upper by so thin an atmosphere that the craft would not be "captured" and therefore would not reenter. Within the atmosphere the Apollo command module will have a limited degree of maneuverability. Although its lift-to-drag ratio is only about 0.34, the reentry path will be 1,000 mi. long and 200 mi. wide as a result of the high entry velocity.

The first manned Apollo flight, in earth orbit, was scheduled for Feb. 1967. On Jan. 27, 1967, during a countdown rehearsal, a fire broke out inside the spacecraft cabin and spread rapidly in the concentrated oxygen environment at sea level pressure. Astronauts Virgil I. Grissom, Edward H. White II and Roger B. Chaffee attempted to escape from the spacecraft but were unable to leave and lost their lives.

5. Manned Spacecraft Design.—Two factors are of major importance in the design of manned spacecraft: weight and reliability. The need for minimum weight becomes apparent when it is recognized that, for a manned lunar mission, 750 lb. of launch vehicle weight is required for every pound returned to Earth at the end of the mission; or, since the takeoff thrust is about 25% higher than the takeoff weight, an additional 1,000 lb. of thrust is needed for each added pound of spacecraft weight. Reliability is generally assured by providing redundant elements where a failure would critically affect the success of the mission. In manned missions the pilot can significantly enhance reliability by detailed failure analyses and corrective actions.

External Characteristics.—The external shape and materials of a manned spacecraft are governed by the necessity of reentering the Earth's atmosphere at speeds approaching satellite or escape velocity, depending on the type of mission. The tremendous heat generated during reentry is dissipated either by radiation from the craft's surface, or by ablating (evaporating or boiling away) some of the surface material. For example, in the Mercury and Gemini spacecraft (fig. 21), the major portion of the heat is dissipated by ablation from the blunt forward-facing heat shield; heat is also rejected from the conical afterbody, where thin (0.016-in.), high-temperature alloy "shingles" quickly reach an equilibrium temperature and give off heat by radiation.

The blunt shape of the forward face of the Mercury, Gemini and Apollo spacecraft also helps in the heat rejection process. This shape creates a strong shock wave which in turn dissipates much of the craft's kinetic energy; therefore, only a small part of the total energy is given off as heat at the vehicle's surface.

Major Subsystems.—Subsystems for providing a habitable atmosphere, for generating electric power, for determining and maintaining the correct attitude, flight path and velocity, and for communications are located inside the spacecraft.

The environmental control system provides oxygen (or air) at the proper temperature, pressure and humidity, and removes carbon dioxide and other contaminants. In all U.S. spacecraft, oxygen at a pressure of 5 p.s.i.a. is used for breathing purposes; in the U.S.S.R. Vostok spacecraft, a standard mixture of oxygen and nitrogen at a pressure of 14.7 p.s.i.a. is employed. Although the cabin atmosphere itself is habitable, the pilot is further protected by a pressure suit which allows him to survive in case the cabin is punctured by a meteoroid or is otherwise damaged.

Electric power sources include ordinary batteries, solar cells and hydrogen-oxygen fuel cells. For short missions, up to two or three days in duration, ordinary batteries are acceptable; for longer missions, solar cells or fuel cells can generate greater amounts of power with lower weight requirements. Fuel cells also produce potable water as a by-product.

The spacecraft's attitude is stabilized with small rocket motors, or thrusters. The thrusters can be fired automatically or manually by the pilot through the use of a control similar to an airplane control stick. Whichever method is chosen, the necessary information concerning the craft's attitude comes from an autopilot, which uses gyroscopes to measure attitudes and attitude changes. In Earth satellite missions it is important to stabilize the craft's attitude precisely about all axes of rotation just prior to retrofire, so that reentry will be made in the proper direction. In rendezvous missions and in lunar missions, attitude control also must be maintained while making course corrections and during docking maneuvers.

Guidance and navigation systems are employed to find the spacecraft's position and velocity in space, to determine course corrections that must be applied to follow the desired trajectory, and to measure changes in speed and direction while maneuvers are made. A typical guidance system consists of an inertial measurement unit (an array of gyroscopes and accelerometers) used to measure the acceleration vectors relative to a fixed point in space, and a guidance computer to translate acceleration measurements into trajectory data and to determine required course corrections. With this information the pilot then applies thrust in the proper direction.

Communications systems in manned spacecraft include voice receivers and transmitters, telemetry receivers and transmitters for sending measurement data, and radar beacons for transmitting tracking information to ground network stations. (G. M. Lo.)

VII. APPLICATIONS

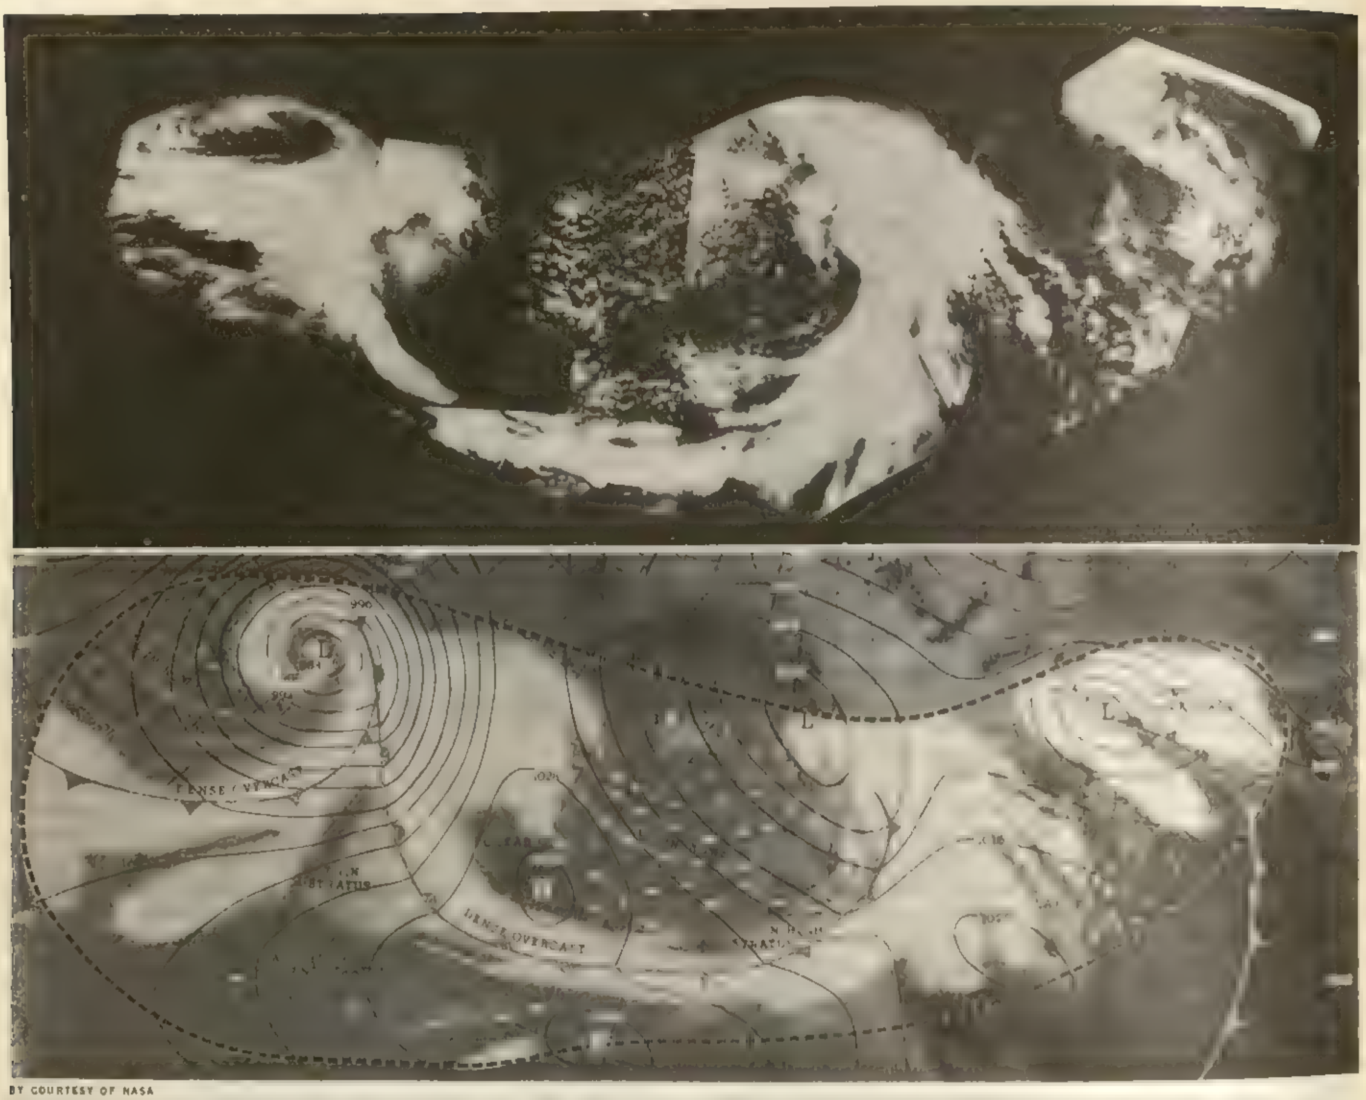
Satellites have several properties which make them uniquely useful: (1) their ability to provide a view of a large portion of the Earth's surface at any instant; (2) their ability to view all of the surface over a period of time if in a nearby polar orbit; and (3) their ability to view continuously the disk of the Earth's surface if in a synchronous orbit. Conversely, a satellite is mutually visible from a large number of widely separated points on the Earth's surface. Results obtained by the first communication, meteorological and geodetic applications satellites pointed the way to other useful applications, including navigation, agriculture and forestry, cartography and geography, and geology and hydrology.

1. Meteorological Satellites.—Satellites such as the Tiros series provide the means to monitor the Earth's cloud cover and temperature distribution. This information is telemetered to data-acquisition stations on the Earth in the forms of television pictures and temperatures as measured with infrared-sensitive radiation detectors. (*See* fig. 22.)

Since weather is affected by conditions over a large portion of the Earth and by the solar energy input to the Earth, it is important that meteorological data be obtained over the entire surface of the Earth. Complete global monitoring was previously impossible because of the many observation stations required and inability to place them in many areas, particularly in the ocean areas where severe weather disturbances originate.

Satellites such as Tiros and Nimbus provided coverage of some of these meteorological events for the first time. Satellite observations have led to the discovery of severe storms, hurricanes and typhoons long before they could be detected by conventional means. The Tiros system has led to the development of the world's first operational weather satellite system. The ESSA 1 and ESSA 2 satellites, operated by the U.S. department of commerce, provide global picture data on a daily basis for use in short-range weather forecasts.

The Nimbus 1 satellite, launched in Aug. 1964, carried an advanced vidicon camera system, a high-resolution infrared radiometer and automatic picture transmission (APT). This satellite sent daytime pictures to simple APT ground stations for local use. Nimbus 2, launched in May 1966, covers 150 APT stations around the clock, including 44 stations in 26 different countries. This satellite has the added capability of transmitting nighttime infrared photographs of cloud cover to specifically modified ground stations. In addition to the utilization of Nimbus data for meteorological research and weather forecasting, the data have been



BY COURTESY OF NASA

FIG. 22.—STORMS AND FRONTS AS SEEN BY TIROS. (TOP) MOSAIC OF TIROS PHOTOGRAPHS; (BOTTOM) WEATHER MAP FOR MAY 20, 1960, PREPARED BY USING TIROS CLOUD DATA

utilized in other areas of research such as glaciology, geology and oceanography.

Meteorological satellites have also led to a new understanding of the tremendously large area of influence of certain weather conditions. There was little doubt that this new capability to observe from above, and over the entire surface of the Earth, would result in better information on which to base weather forecasting and lead to a more thorough understanding of the nature of the weather processes, all of which would make the interpretation of observations more accurate. Meteorological satellites will place greater emphasis on remote sensing of the atmosphere to obtain the information that will make it possible to extend weather forecasting to two to three weeks in advance.

2. Communications Satellites.—Another promising application of satellites, which takes advantage of the property that satellites can be seen simultaneously from widely separated points on the earth, was first proposed in 1945 by Arthur C. Clarke. He suggested the use of a manned satellite station for relaying communications over large distances. Although they were unmanned, the Echo, Telstar, Relay and Syncom satellites demonstrated the utility of this means of communication.

Satellite Coverage.—Satellites such as Telstar and Relay are in intermediate-altitude orbits (3,000 to 6,000 mi. high) and therefore move with respect to the Earth. Thus, to provide continued communications between two widely separated points would require that satellites passing out of range be replaced by other satellites just coming into view. From 30 to 50 satellites would be required at these altitudes to provide essentially continuous communications, if the satellites were distributed randomly with respect to each other in their orbits.

The Syncom satellite was placed in an orbit at an altitude of 22,245 mi. At this altitude the period of rotation of the satellite about the Earth is exactly 24 hr. By selecting an equatorial orbit and a period that is the same as the Earth's rotational period, the satellite remains stationary or fixed relative to the surface of the Earth. Thus a single "synchronous" satellite of this type would be available continuously for communications between any two stations within its area of visibility, and three such satellites, suitably spaced, could provide global coverage with the exception of the extreme polar regions.

Types of Communications Satellites.—Telstar, Relay and Syncom are all "active" satellites; *i.e.*, they carry transmitter-receiver sets to receive, amplify and retransmit signals from the ground, as well as the necessary power supplies. There are also "passive" communications satellites which carry no electronics equipment but merely reflect a signal directed at them back toward the Earth. Examples are the 100-ft. inflatable sphere Echo I which was visible as a rapidly moving "star" in the evening skies, and its successor, Echo 2. Passive satellites require larger receiving antennas on the ground and larger amounts of ground transmitter power than active satellites because they reflect only a small fraction of the incident energy back to the receiving antenna.

Commercial Communications Satellites.—The successful development and demonstration of these satellites paved the way for a new era in commercial communications. The Communication Satellite corporation (Comsat), authorized by the U.S. congress in

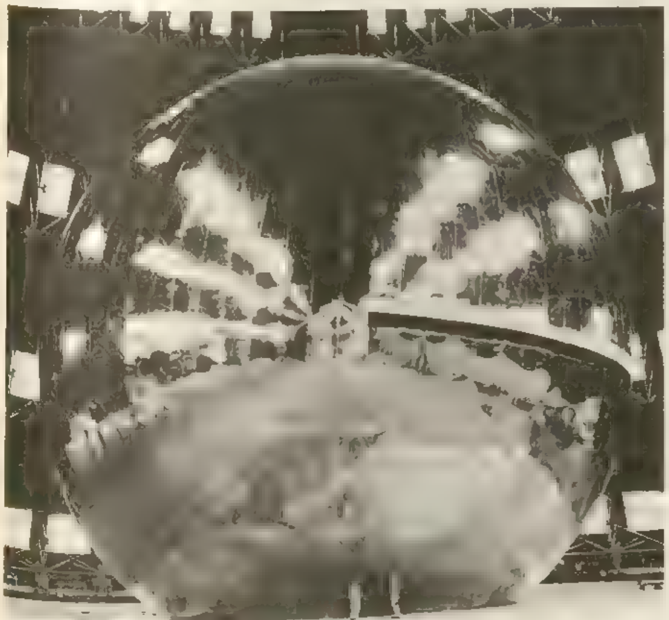
1962, and incorporated in Feb. 1963, was created to establish a global commercial communication satellite system. Comsat acts as the system manager for the International Telecommunication Satellite Consortium ("Intelsat")—the name adopted to describe the participants in the interim international arrangements for the financing and ownership of the space segment of the system.

Comsat's first satellite (Early Bird) was launched by NASA in April 1965 and placed in synchronous orbit over the Atlantic for operation between North America and Europe. Early Bird was placed in commercial operation in June 1965 and provides a basic capability of 240 transatlantic telephone channels. It has also been used for the transmission of television between the two continents.

Comsat was preparing to launch additional satellites in 1966 to support NASA's Apollo program (manned flight to the Moon). These satellites were to also provide circuits for commercial use and were to be placed in synchronous orbit over the Atlantic and Pacific oceans. It was planned that the first launchings of a truly global communication satellite system would begin in 1968.

3. Navigation and Data Collection Satellites.—Advances in space technology have made it possible to envision an Earth-orbiting satellite to achieve a new and improved worldwide, all-weather navigation system for use in sea and air traffic control and for the global collection of data pertinent to traffic routing and safety. Satellites, together with an associated ground station complex and transponders in craft using the system, have the potential capability of providing accurate position information automatically, quickly and reliably to commercial sea and air traffic, to control and routing centres and to air-sea rescue stations. Satellites could also augment this position data with weather forecasts, ocean sea-state reports and other information to ensure safety to both sea and air lanes. Direct long-distance voice communications between traffic controllers and the craft, and distress messages advising controllers of disabled craft location and situation could be provided by a communications channel in the satellite. Research and development work to determine the feasibility of such a satellite was planned for the mid- and late 1960s.

4. Geodetic Satellites.—The first satellite whose major objective was geodesy was ANNA 1-B launched in Oct. 1962. It contained three independent instrumentation systems to provide an increase in the quality of observational data, to permit the comparison of simultaneous measurements and to enable an integrated analysis of all the data. In Aug. 1964, the National Geodetic Satellite Program was initiated with the following objectives:



PICTORIAL PARADE

FIG. 23.—ECHO 1, A HIGH-ALTITUDE REFLECTOR FOR LONG-RANGE COMMUNICATIONS, SHOWN HERE DURING GROUND INFLATION TESTS. THE ALUMINUM-COATED BALLOON, WHICH INFLATES TO 100 FT. IN DIAMETER, WAS LAUNCHED AUG. 12, 1960

WIDE WORLD

FIG. 24.—TELSTAR 1, FIRST PRIVATELY OWNED COMMUNICATIONS SATELLITE, WAS LAUNCHED IN 1962, MAKING POSSIBLE THE TRANSMISSION OF LIVE TELEVISION PROGRAMS BETWEEN THE U.S. AND EUROPE

(1) connect geodetic datums to establish one world datum and adjust all local datums to the common centre-of-mass of the Earth so that positions of geodetic control stations will have a relative accuracy of ± 10 m. or better in an Earth centre-of-mass coordinate system; (2) define the structure of the Earth's gravitational field to 5 parts in 100,000,000 and refine the locations and magnitude of large gravity anomalies; (3) compare and correlate geodetic systems for an integrated analysis; and (4) further refine the positions of tracking stations relative to each other and relative to an improved world geodetic reference system.

To realize these objectives both optical and electronic systems, stationary and portable, are utilized to obtain tracking data from both active and passive satellites. The active geodetic satellites are the Beacon Explorers-B and -C, and GEOS-A and -B. The passive PAGEOS is a 100-ft. diameter sun-reflective balloon. The Beacon Explorers and GEOS-A have already been placed in orbit at altitudes of about 620 mi. PAGEOS was launched in June 1966 into a 2,635-mi. orbit.

Completed studies show that the Earth is an unsymmetrical oblate spheroid with differences in geoid heights of as much as ± 100 m. It is also evident that its shape, size and mass are sufficiently well known for most purposes. Small uncertainties in values for flattening of the Earth and the semi-major axis are significant, however, for space and scientific activities. Better information on the distribution of the Earth's mass and gravity, plus more accurate positions and an improved world geodetic datum, will permit more accurate deep space launches with less need for mid-course and terminal guidance corrections.

Advanced geodetic satellites now being investigated will use new observational systems such as hybrid ground stations, radar altimeters, gravity-gradiometers and other spacecraft-borne sensors. Resulting data will give important support to other scientific disciplines such as geophysics, geology, oceanography and celestial mechanics.

5. Earth Resource Survey Satellites.—It has been demon-

strated by such space programs as Tiros, Nimbus and Gemini that some of the Earth's natural and cultural resources can be surveyed more advantageously from space than by other means. Resources which can be surveyed in this manner include mineral districts, soils and soil moisture, crops, timber stands, certain types of marine life and metropolitan land and transportation networks. Advantages which satellites possess for Earth resource surveys include: rapidity and continuity of observations, reduced data acquisition times, synoptic views for regional syntheses, and greater freedom from weather disturbances.

To maintain world economic developments at their present levels requires continued assessment and utilization of the Earth's resources. Satellite surveys appear to be the only feasible way to complete and keep up-to-date worldwide resource maps within the foreseeable future. The Earth resource satellites of the future are expected to incorporate instrumentation capable of scanning the full electromagnetic spectrum from radio waves through the visible to the infrared and ultraviolet regions. These instruments are expected to reveal for the first time the full potential of the Earth in terms of those natural resources which have direct and real benefit to mankind. (L. JA.)

VIII. INTERNATIONAL SPACE ACTIVITIES

The space age began in an atmosphere of international co-operation. Following suggestions made in Rome in 1954 by the central planning body, Comité Spéciale de l'Année Géophysique Internationale (CSAGI), for the International Geophysical Year, the U.S. and the U.S.S.R. announced plans for artificial scientific satellites. Both countries, plus the United Kingdom, Canada, Japan, Australia and France (unofficially), also organized programs for the launching of small, scientific sounding rockets.

CSAGI subsequently considered resolutions for the exchange of satellite and sounding-rocket information consistent with the open, scientific character of the IGY. The western members sought the widest possible exchange of information relating to experiments and results. Soviet scientists preferred to restrict the resolutions essentially to published scientific results. The fact that the tools, techniques and certain of the research objectives of space research were common to both scientific and military interests was clearly a limiting factor.

Scientists of countries concerned with satellites or sounding-rocket work, including tracking, met with delegates from interested international scientific unions in London in Nov. 1958 to draft a charter for a permanent International Committee for Space Research (COSPAR) to function under the International Council of Scientific Unions. The meeting was convened by Homer E. Newell of the United States. The group formulated a charter and selected H. C. Van de Hulst of the Netherlands as president. Representatives of the U.S.S.R. Academy of Sciences participated in the drafting of the charter, but at the next meeting of COSPAR, in March 1959 in The Hague, they alleged that the charter gave inadequate "representation" to the eastern bloc.

Other delegates strongly opposed overt consideration of political factors in the organization of a nongovernmental scientific body. A compromise provided for two vice-presidents, one each from the U.S. and the U.S.S.R., with additional members of COSPAR's executive committee to be selected from slates proposed by the two countries.

COSPAR subsequently met amicably in Nice, France (1960), Florence, Italy (1961 and 1964), Washington, D.C. (1962), and Warsaw, Pol. (1963). Little change was made in the original IGY patterns for exchange of data and notification of launchings. While other nations went well beyond the IGY-COSPAR conventions for co-operation, the Soviet Union in general continued to publish scientific results often lacking sufficient detail for independent evaluation, listed "look-angles" for satellites at specific locations but failed to provide their orbital elements, and furnished only general information on numbers of sounding rockets launched in various areas, without listing experiments or results. Catalogues of rocket-satellite data deposited in the IGY World Data centre in Moscow were to have been provided at six-month intervals but were not made available after 1960. Only an approximate compliance with the fundamental requirement for information of scientific results can be said to have been obtained.

Beginning in 1962 COSPAR attempted to modify its structure so as to make a positive contribution to the organization of useful space research. Significant progress became evident by 1963 in the planning of synoptic sounding-rocket programs in meteorology, ionospherics and aeronomy.

Another forum, principally for annual symposia on engineering aspects of space research, exists in the International Astronautical federation, which brings together a considerable number of national rocket societies with broad and long-standing interests in the promotion of space exploration.

1. U.S. Programs of Co-operation.—The charter of the National Aeronautics and Space administration provided, among its objectives, for co-operation with other nations in space activities. Co-operation was offered by NASA with officially sponsored, central civilian agencies in other countries, with literal sharing of the requirements for specific projects of scientific validity and mutual interest, without exchange of funds. The program included:

Joint Satellite Projects.—The first international satellites were Ariel and Alouette, the former instrumented in the U.K. and engineered by NASA, the latter prepared entirely in Canada, and both launched successfully in 1962 by NASA. By the end of 1964 a second British and a first Italian satellite had been successfully launched, the latter by an Italian team using U.S. launch facilities. Additional co-operative satellites were planned by British, French and Italian national space councils. Under a 1964 agreement, NASA undertook the launching, in 1967, of two satellites to be prepared by the European Space Research organization (*see* below).

In Nov. and Dec. 1965, a second Canadian and a first French satellite were launched by the U.S. Also, in 1965, a bilateral agreement was negotiated by NASA and the West German ministry of science for a joint scientific satellite project in 1968. A project involving NASA and the French Space committee was agreed upon in June 1966. It provided for a French satellite launched by NASA to work in conjunction with high-altitude balloons, deriving wind and temperature information from them.

Individual Satellite Experiments.—A number of experiments proposed by scientists outside of the U.S. and judged in competition with U.S. proposals were selected by NASA for incorporation in large observatory satellites to be launched over a period of several years.

Sounding Rocket Experiments.—Australia, Canada, India, Italy, Japan, New Zealand, Pakistan, Denmark, Norway, Sweden, France, the Netherlands and Argentina co-operated with NASA in the launching of scientific sounding rockets, from sites in several countries. Responsibility was divided for the essential components: sounding rockets, payloads and ground equipment. Countries which more recently entered joint programs of this type include Brazil, Germany, Spain and the U.K.

Ground-Based Experimental Participation.—More than 40 countries carried out weather observations made with aircraft, balloons or ground instruments, synchronized for correlation purposes with cloud photographs obtained by NASA's Tiros weather satellites; 10 countries established major ground terminals for experimental communications by means of NASA communications satellites.

Tracking and Data-Acquisition Operations.—About two-thirds of NASA stations outside the U.S. are operated wholly or in part by citizens of the host countries, which, in a number of cases, also provide and support the technical staff.

Training.—Three NASA programs offer (1) graduate fellowships at U.S. universities for students sponsored by their central space agencies; (2) training arrangements at NASA centres in support of agreed co-operative projects; and (3) associateships at NASA centres for gifted senior scientists.

2. U.S.–U.S.S.R. Relationships.—United States representatives attempted during the IGY to broaden exchanges between the two major space powers but met with little success. Other bilateral overtures were made privately, and in 1960 NASA publicly offered tracking services by Project Mercury stations for future Soviet manned flights. The offer was not accepted.

In Feb. and March 1962 Pres. John F. Kennedy responded

to routine congratulations from Chairman Nikita S. Khrushchev, on the occasion of the first U.S. manned orbital flight, by proposing specific co-operative projects and designating Hugh L. Dryden, deputy administrator of NASA, as chief negotiator. Khrushchev designated Soviet academician A. A. Blagonravov to meet with Dryden. By June 1962 their discussions produced an agreement calling for co-ordinated weather satellite launchings and data exchange, a complementary satellite survey of the Earth's magnetic field, and demonstration of experimental space communications by means of the U.S. satellite Echo 2. By Aug. 1963 a detailed implementing agreement became effective.

With increasing strength in the U.S. space program and the easing of international tension following the nuclear test ban treaty of 1963, President Kennedy was encouraged to suggest, in his speech to the general assembly of the United Nations in Sept. 1963, that the two countries explore co-operation in their manned lunar programs.

The bilateral agreement of 1962 led, early in 1964, to communication tests by means of Echo 2, conducted through transmissions from a U.K. station to a Soviet station. The Soviet side provided data on the tests. By Oct. 1964 a conventional communications link for exchanging weather data was operating between Washington and Moscow on a shared cost basis. Conventional weather data was being exchanged twice daily but satellite data was not yet exchanged since it was not yet available from the Soviet side.

3. European Regional Co-operation.—In the period 1961–63, 9 countries established a European Space Research organization (ESRO) to develop scientific satellites and employ sounding rockets. By late 1963 plans had been made for a budget of $300,000,000 over an eight-year period, and for the establishment of a data centre in Darmstadt, Ger., a technical centre in Delft, Neth., and a test centre in Italy, as well as administrative headquarters in Paris. ESRO member countries were the United Kingdom, France, West Germany, Spain, Switzerland, Denmark, Sweden, Belgium and the Netherlands. Among the ESRO projects were development of two small satellites to be launched by NASA, two medium satellites to be launched by boosters purchased through NASA and a large astronomical satellite to be launched by the ELDO vehicle (*see* below).

A second agency, the European Launcher Development organization (ELDO), was organized during the same period. Consisting of seven countries, including Australia, ELDO sought to develop a European satellite booster using the British Blue Streak vehicle as a first stage, a French second stage and a German third stage. Belgium, the Netherlands and Italy were the other participants. ELDO's budget called for expenditures of about $200,000,000 over five years. Its launching range was planned at Woomera, Austr. The first stage of the Blue Streak was successfully flight-tested in 1964. In early 1966, rumours of British withdrawal from ELDO precipitated a crisis in European space affairs. It was expected to be resolved through a review of costs to reduce the U.K. share and a reshaping of the program to provide an early capability to launch a synchronous communications satellite.

4. UN Activities.—Following a U.S. proposal, the United Nations established an *ad hoc* committee on the peaceful uses of outer space in 1959. The Soviet Union, the United Arab Republic and India abstained, essentially on issues of political representation and procedure. The committee prepared a report describing the opportunities for useful activity by UN specialized agencies such as the World Meteorological organization and the International Telecommunications union, stating opportunities for the development of space law and seeking to encourage co-operation among nations in peaceful space research. By late 1961 a formula was arrived at which expanded the committee, increasing the representation of the eastern bloc, and provided for the committee to attempt to do its business on the basis of unanimity. Designated the UN Committee on the Peaceful Uses of Outer Space, it established two subcommittees, one on scientific and technical matters, the other on legal matters. It was agreed that the committee's function would be to facilitate co-operation among nations rather than engage in operational activities. The Scientific and Technical subcommittee met in Geneva, Switz., in mid-1962 and recommended the publication of information on national program activities, requested support for specific programs of the international scientific community and provided for possible UN sponsorship of an international sounding-rocket range to be established on the geomagnetic equator. India offered to establish such a range, then in preparation through bilateral arrangements with the United States. The parent committee unanimously approved the Scientific and Technical subcommittee's report in September, and the general assembly added its approval later in the fall of 1962. Although the subcommittee reconvened in Geneva in the spring of 1963 and again in 1964, little more was accomplished other than the receipt and preparation of various reports. The international rocket sounding range at Thumba in India did, however, progress well, receiving U.S., French and Soviet contributions in the form of equipment. While reflecting Soviet political inhibitions in part, the absence of further substantive achievement also could be ascribed to the limited scope available at the time for UN activity within its prescribed nonoperational function.

Early in 1966, an *ad hoc* working group met in New York and agreed on a UN International Conference on the Peaceful Uses of Outer Space to meet in 1967. Also in 1966, first the United States and then the Soviet Union proposed treaties to preserve celestial bodies exclusively for peaceful purposes. It was agreed that the Legal subcommittee of the UN space committee would convene in Geneva in July 1966 to attempt to draft such a treaty.

5. Prospects.—Despite political and security difficulties, unexpected progress was made in the first six years of the space age in bringing nations together in useful co-operation of more than token character. The bulk of substantive activity followed from the international co-operative projects of NASA. However, other centres of international collaboration began to appear. The regional organizations in Europe, ELDO and ESRO, mapped ambitious programs. The International Committee on Space Research (COSPAR) began to generate useful operational activities pursuant to recommendations made by certain of its working groups. The first steps taken toward significant co-ordination of effort by the Soviet Union and the United States, however, although giving early promise, tended to lose momentum and lag as the U.S.S.R. responded slowly to U.S. overtures. (A. W. FR.)

IX. SPACE LAW

It was apparent from the outset of the era of space flight that the legal status of outer space must differ essentially from that of air space. It is a universally recognized principle of international law that every nation has complete and exclusive sovereignty over the air space above its territory and therefore possesses the right to exclude aircraft from its air space and to determine unilaterally the conditions of entry and use, unless a different rule has been prescribed by an international agreement to which the nation is a party. The vertical extent of the air space has never been defined by international agreement and there is no agreed limit upon the upward reach of the area within which the underlying nation may exercise exclusive control.

If the rule of exclusive sovereignty which prevails in the air space were to extend to altitudes at which orbital flight can be accomplished, it would be necessary to secure the prior consent of nations over which a satellite would pass. In apparent reliance, however, on a basic difference between the legal status of air space and the legal status of outer space, no nation has sought the prior consent of other nations before sending its satellites aloft. No objection was registered by any other nation.

In addition to the question of the legal status of outer space, the related question of the legal status of celestial bodies was raised by the prospect of exploration and exploitation of the Moon and the planets of the solar system.

Both of these questions were the subject of Resolution 1721 (XVI) adopted unanimously by the general assembly of the United Nations on Dec. 20, 1961. The resolution, which was the first authoritative statement of legal principles applicable to space activities, "commends to States for their guidance" the principles that "international law, including the Charter of the United Nations, applies to outer space and celestial bodies" and that "outer

space and celestial bodies are free for exploration and use by all States in conformity with international law and are not subject to national appropriation."

Resolution 1721 (XVI) also requested the United Nations Committee on the Peaceful Uses of Outer Space "to study and report on the legal problems which may arise from the exploration and use of outer space." During the two years after the adoption of the resolution, a consensus on certain general principles emerged from the deliberations of the committee and its Legal subcommittee. These principles were given formal expression in Resolution 1962 (XVIII), entitled "Declaration of Legal Principles Governing the Activities of States in the Exploration and Use of Outer Space," which was adopted unanimously by the general assembly on Dec. 13, 1963.

In addition to restating the principles enunciated in Resolution 1721 (XVI), Resolution 1962 (XVIII) declared that states bear international responsibility for national activities in outer space, whether carried on by governmental agencies or by nongovernmental entities; that the activities of nongovernmental entities in outer space require authorization and continuing supervision by the state concerned; that each state which launches or procures the launching of an object into outer space, and each state from whose territory or facility an object is launched, is internationally liable for damage caused by such object to a foreign state or to its natural or juridical persons on the Earth, in air space or in outer space; that the state of registry of an object launched into outer space retains jurisdiction and control over the object and its personnel while in outer space; that ownership of objects launched into outer space is not affected by their passage through outer space or by their return to Earth, and there is a duty to return any such object to the state of registry regardless of the place where found; and that personnel engaging in space flight who make a landing on the territory of a foreign state or on the high seas because of accident or emergency shall be safely and promptly returned to the state of registry.

Resolution 1962 (XVIII) recognized that activities in outer space might be carried on by international organizations, and it provided that in such cases responsibility for compliance with the principles set forth in the resolution shall be borne by the international organization and by the states participating in it. Taking account of the possibility of harmful interference being caused by a particular space activity with the activities of other states in the peaceful exploration and use of outer space, the resolution declared that if a state has reason to believe that an outer space activity planned by it or its nationals would have such an adverse effect, it shall undertake appropriate international consultations before proceeding with any such activity.

Although both Resolution 1721 (XVI) and Resolution 1962 (XVIII) declared the principle that outer space is free and is not subject to national appropriation, neither resolution attempted to define at what altitude outer space begins or air space ends. The problem presented by the apparent juxtaposition of two realms governed by antithetical legal regimes was left by the general assembly for future consideration. It appeared that the future development of manned space flight, involving extensive flight during return to earth at altitudes below that at which orbital flight can occur but above that at which the flight of conventional aircraft has taken place, eventually would require a more precise treatment of this question. (J. A. Jo.)

SPACE-TIME. The theory of relativity has brought about a fundamental change in the scientific conception of space and time, described in a famous saying of Hermann Minkowski—"From henceforth space in itself and time in itself sink to mere shadows, and only a kind of union of the two preserves an independent existence." This union is called space-time. In this article, the concept itself is discussed first by Albert Einstein. Recent developments are summarized in the section that follows Einstein's contribution. The method of determining the structure of space-time is described in the article RELATIVITY.—Editor.

EINSTEIN'S CONCEPTS

All our thoughts and concepts are called up by sense experiences and have a meaning only in reference to these sense experiences. On the other hand, however, they are products of the spontaneous activity of our minds; they are thus in no wise logical consequences of the contents of these sense experiences. If, therefore, we wish to grasp the essence of a complex of abstract notions we must for the one part investigate the mutual relationships between the concepts and the assertions made about them; for the other, we must investigate how they are related to the experiences.

As far as the way is concerned in which concepts are connected with one another and with the experiences there is no difference of principle between the concept systems of science and those of daily life. The concept systems of science have grown out of those of daily life and have been modified and completed according to the objects and purposes of the science in question.

The more universal a concept is, the more frequently it enters into our thinking; and the more indirect its relation to sense experience, the more difficult it is for us to comprehend its meaning; this is particularly the case with prescientific concepts that we have been accustomed to use since childhood. Consider the concepts referred to in the words "where," "when," "why," "being," to the elucidation of which innumerable volumes of philosophy have been devoted. We fare no better in our speculations than a fish which should strive to become clear as to what is water.

SPACE

In the present article we are concerned with the meaning of "where," that is, of space. It appears that there is no quality contained in our individual primitive sense experiences that may be designated as spatial. Rather, what is spatial appears to be a sort of order of the material objects of experience. The concept "material object" must therefore be available if concepts concerning space are to be possible. It is the logically primary concept. This is easily seen if we analyze the spatial concepts for example, "next to," "touch," and so forth, that is, if we strive to become aware of their equivalents in experience. The concept "object" is a means of taking into account the persistence in time or the continuity, respectively, of certain groups of experience complexes. The existence of objects is thus of a conceptual nature, and the meaning of the concepts of objects depends wholly on their being connected (intuitively) with groups of elementary sense experiences. This connection is the basis of the illusion which makes primitive experience appear to inform us directly about the relation of material bodies (which exist, after all, only insofar as they are thought).

In the sense thus indicated we have (the indirect) experience of the contact of two bodies. We need do no more than call attention to this, as we gain nothing for our present purpose by singling out the individual experiences to which this assertion alludes. Many bodies can be brought into permanent contact with one another in manifold ways. We speak in this sense of the position relationships of bodies (*Lagenbeziehungen*). The general laws of such position relationships are essentially the concern of geometry. This holds, at least, if we do not wish to restrict ourselves to regarding the propositions that occur in this branch of knowledge merely as relationships between empty words that have been set up according to certain principles.

Prescientific Thought.—Now, what is the meaning of the concept "space" which we also encounter in prescientific thought? The concept of space in prescientific thought is characterized by the sentence: "We can think away things but not the space which

they occupy." It is as if, without having had experience of any sort, we had a concept, nay, even a presentation, of space; and as if we ordered our sense experiences with the help of this concept, present a priori. On the other hand, space appears as a physical reality, as a thing which exists independently of our thought, like material objects. Under the influence of this view of space the fundamental concepts of geometry, the point, the straight line, the plane, were even regarded as having a self-evident character. The fundamental principles that deal with these configurations were regarded as being necessarily valid and as having at the same time an objective content. No scruples were felt about ascribing an objective meaning to such statements as "three empirically given bodies (practically infinitely small) lie on one straight line," without demanding a physical definition for such an assertion. This blind faith in evidence and in the immediately real meaning of the concepts and propositions of geometry became uncertain only after non-Euclidean geometry had been introduced.

Reference to the Earth.—If we start from the view that all spatial concepts are related to contact experiences of solid bodies, it is easy to understand how the concept "space" originated, namely, how a thing independent of bodies and yet embodying their position possibilities (*Lagerungsmöglichkeiten*) was posited. If we have a system of bodies in contact and at rest relatively to one another, some can be replaced by others. This property of allowing substitution is interpreted as "available space." Space denotes the property in virtue of which rigid bodies can occupy different positions. The view that space is something with a unity of its own is perhaps due to the circumstance that in prescientific thought all positions of bodies were referred to one body (reference body), namely the earth. In scientific thought the earth is represented by the coordinate system. The assertion that it would be possible to place an unlimited number of bodies next to one another denotes that space is infinite. In prescientific thought the concepts "space" and "time" and "body of reference" are scarcely differentiated at all. A place or point in space is always taken to mean a material point on a body of reference.

Euclidean Geometry.—If we consider Euclidean geometry we clearly discern that it refers to the laws regulating the positions of rigid bodies. It turns to account the ingenious thought of tracing back all relations concerning bodies and their relative positions to the very simple concept "distance" (*Strecke*). Distance denotes a rigid body on which two material points (marks) have been specified. The concept of the equality of distances (and angles) refers to experiments involving coincidences; the same remarks apply to the theorems on congruence. Now, Euclidean geometry, in the form in which it has been handed down to us from Euclid, uses the fundamental concepts "straight line" and "plane" which do not appear to correspond, or at any rate, not so directly, with experiences concerning the position of rigid bodies. (On this it must be remarked that the concept of the straight line may be reduced to that of the distance. A hint of this is contained in the theorem: "The straight line is the shortest connection between two points." This theorem served well as a definition of the straight line, although the definition played no part in the logical texture of the deductions.) Moreover, geometricians were less concerned with bringing out the relation of their fundamental concepts to experience than with deducing logically the geometrical propositions from a few axioms enunciated at the outset.

Let us outline briefly how perhaps the basis of Euclidean geometry may be gained from the concepts of distance. We start from the equality of distances (axiom of the equality of distances). Suppose that of two unequal distances one is always greater than the other. The same axioms are to hold for the inequality of distances as hold for the inequality of numbers. Three distances $\overline{AB'}$, $\overline{BC'}$, $\overline{CA'}$ may, if CA' be suitably chosen, have their marks BB', CC', AA' superposed on one another in such a way that a triangle ABC results. The distance CA' has an upper limit for which this construction is still just possible. The points A, (BB') and C then lie in a "straight line" (definition). This leads to the concepts: producing a distance by an amount equal to itself; dividing a distance into equal parts; expressing a distance in terms of a number by means of a measuring rod (definition of the space interval between two points).

When the concept of the interval between two points or the length of a distance has been gained in this way we require only the following axiom (Pythagoras' theorem) in order to arrive at Euclidean geometry analytically. To every point of space (body of reference) three numbers (coordinates) x, y, z may be assigned —and conversely—in such a way that for each pair of points A (x_1, y_1, z_1) and B (x_2, y_2, z_2) the theorem holds:

$$\text{measure number } AB = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}$$

All further concepts and propositions of Euclidean geometry can then be built up purely logically on this basis, in particular also the propositions about the straight line and the plane. These remarks are not, of course, intended to replace the strictly axiomatic construction of Euclidean geometry. We merely wish to indicate plausibly how all conceptions of geometry may be traced back to that of distance. We might equally well have epitomized the whole basis of Euclidean geometry in the last theorem above. The relation to the foundations of experience would then be furnished by means of a supplementary theorem. The coordinate may and *must* be chosen so that two pairs of points separated by equal intervals, as calculated by the help of Pythagoras' theorem, may be made to coincide with one and the same suitably chosen distance (on a solid). The concepts and propositions of Euclidean geometry may be derived from Pythagoras' proposition without the introduction of rigid bodies; but these concepts and propositions would not then have contents that could be tested. They are not "true" propositions but only logically correct propositions of purely formal content.

Difficulties.—A serious difficulty is encountered in the above represented interpretation of geometry in that the rigid body of experience does not correspond *exactly* with the geometrical body. There are no absolutely definite marks, and, moreover, temperature, pressure, and other circumstances modify the laws relating to position. It is also to be recollected that the structural constituents of matter (such as atom and electron, *qq.v.*) assumed by physics are not in principle commensurate with rigid bodies, but that nevertheless the concepts of geometry are applied to them and to their parts. For this reason consistent thinkers have been disinclined to allow real contents of facts (*reale Tatsachenbestände*) to correspond to geometry alone. They considered it preferable to allow the content of experience (*Erfahrungsbestände*) to correspond to geometry and physics conjointly.

This view is certainly less open to attack than the one represented above; as opposed to the atomic theory it is the only one that can be consistently carried through. Nevertheless it would not be advisable to give up the first view, from which geometry derives its origin. This connection is essentially founded on the belief that the ideal rigid body is an abstraction that is well rooted in the laws of nature.

Foundations of Geometry.—We come now to the question: what is a priori certain or necessary, respectively in geometry (doctrine of space) or its foundations? Formerly we thought everything; nowadays we think—nothing. Already the distance concept is logically arbitrary; there need be no things that correspond to it, even approximately. Something similar may be said of the concepts straight line, plane, of three-dimensionality and of the validity of Pythagoras' theorem. Even the continuum doctrine is in no wise given with the nature of human thought, so that from the epistemological point of view no greater authority attaches to the purely topological relations than to the others (*see* Geometry; Knowledge, Theory of).

Earlier Physical Concepts.—We have yet to deal with those modifications in the space concept which have accompanied the advent of the theory of relativity. For this purpose we must consider the space concept of the earlier physics from a point of view different from that above. If we apply the theorem of Pythagoras to infinitely near points, it reads

$$ds^2 = dx^2 + dy^2 + dz^2$$

where ds denotes the measurable interval between them. For

an empirically given ds the coordinate system is not yet fully determined for every combination of points by this equation. Besides being translated, a coordinate system may also be rotated. This signifies analytically: The relations of Euclidean geometry are covariant with respect to linear orthogonal transformations of the coordinates.

In applying Euclidean geometry to prerelativistic mechanics a further indeterminateness enters through the choice of the coordinate system: the state of motion of the coordinate system is arbitrary to a certain degree, namely, in that substitutions of the coordinates of the form

$$x' = x - vt$$
$$y' = y$$
$$z' = z$$

also appear possible. On the other hand, earlier mechanics did not allow coordinate systems to be applied of which the states of motion were different from those expressed in these equations. In this sense we speak of "inertial systems." In these favoured inertial systems we are confronted with a new property of space as far as geometrical relations are concerned. Regarded more accurately, this is not a property of space alone but of the four-dimensional continuum consisting of time and space conjointly.

Appearance of Time.—At this point time enters explicitly into our discussion for the first time. In their applications space (place) and time always occur together. Every event that happens in the world is determined by the space coordinates x, y, z, and the time coordinate t. Thus the physical description was four-dimensional right from the beginning. But this four-dimensional continuum seemed to resolve itself into the three-dimensional continuum of space and the one-dimensional continuum of time. This apparent resolution owed its origin to the illusion that the meaning of the concept "simultaneity" is self-evident, and this illusion arises from the fact that we receive news of near events almost instantaneously owing to the agency of light.

This faith in the absolute significance of simultaneity was destroyed by the law regulating the propagation of light in empty space or, respectively, by the Maxwell-Lorentz electrodynamics. Two infinitely near points can be connected by means of a light signal if the relation

$$ds^2 = c^2dt^2 - dx^2 - dy^2 - dz^2 = 0$$

holds for them. It further follows that ds has a value which, for arbitrarily chosen infinitely near space-time points, is independent of the particular inertial system selected. In agreement with this we find that for passing from one inertial system to another, linear equations of transformation hold which do not in general leave the time values of the events unchanged. It thus became manifest that the four-dimensional continuum of space cannot be split up into a time continuum and a space continuum except in an arbitrary way. This invariant quantity ds may be measured by means of measuring rods and clocks.

Four-dimensional Geometry.—On the invariant ds a four-dimensional geometry may be built up which is in a large measure analogous to Euclidean geometry in three dimensions. In this way physics becomes a sort of statics in a four-dimensional continuum. Apart from the difference in the number of dimensions the latter continuum is distinguished from that of Euclidean geometry in that ds^2 may be greater or less than zero. Corresponding to this we differentiate between timelike and spacelike line elements. The boundary between them is marked out by the element of the "light-cone" $ds^2 = 0$ which starts out from every point. If we consider only elements which belong to the same time value, we have

$$-ds^2 = dx^2 + dy^2 + dz^2$$

These elements ds may have real counterparts in distances at rest and, as before, Euclidean geometry holds for these elements.

Effect of Relativity, Special and General.—This is the modification which the doctrine of space and time has undergone through the restricted theory of relativity. The doctrine of space has been still further modified by the general theory of relativity, because this theory denies that the three-dimensional spatial section of the space-time continuum is Euclidean in character. Therefore it asserts that Euclidean geometry does not hold for the relative positions of bodies that are continuously in contact.

For the empirical law of the equality of inertial and gravitational mass led us to interpret the state of the continuum, insofar as it manifests itself with reference to a noninertial system, as a gravitational field, and to treat noninertial systems as equivalent to inertial systems. Referred to such a system, which is connected with the inertial system by a nonlinear transformation of the coordinates, the metrical invariant ds^2 assumes the general form:

$$ds^2 = \sum_{\mu\nu} g_{\mu\nu} dx_\mu dx_\nu$$

where the $g_{\mu\nu}$'s are functions of the coordinates and where the sum is to be taken over the indices for all combinations 11, 12, . . . 44. The variability of the $g_{\mu\nu}$'s is equivalent to the existence of a gravitational field. If the gravitational field is sufficiently general it is not possible at all to find an inertial system, that is, a coordinate system with reference to which ds^2 may be expressed in the simple form given above:

$$ds^2 = c^2dt^2 - dx^2 - dy^2 - dz^2$$

but in this case, too, there is in the infinitesimal neighbourhood of a space-time point a local system of reference for which the last-mentioned simple form for ds holds. This state of the facts leads to a type of geometry which Riemann's genius created more than half a century before the advent of the General Theory of Relativity of which Riemann divined the high importance for physics.

Riemann's Geometry.—Riemann's geometry of an n-dimensional space bears the same relation to Euclidean geometry of an n-dimensional space as the general geometry of curved surfaces bears to the geometry of the plane. For the infinitesimal neighbourhood of a point on a curved surface there is a local coordinate system in which the distance ds between two infinitely near points is given by the equation

$$ds^2 = dx^2 + dy^2$$

For any arbitrary (Gaussian) coordinate system, however, an expression of the form

$$ds^2 = g_{11}dx^2 + 2g_{12}dx_1dx_2 = g_{22}dx_2^2$$

holds in a finite region of the curved surface. If the $g_{\mu\nu}$'s are given as functions of x_1 and x_2 the surface is then fully determined geometrically. For from this formula we can calculate for every combination of two infinitely near points on the surface the length ds of the minute rod connecting them; and with the help of this formula all networks that can be constructed on the surface with these little rods can be calculated. In particular, the "curvature" at every point of the surface can be calculated; this is the quantity that expresses to what extent and in what way the laws regulating the positions of the minute rods in the immediate vicinity of the point under consideration deviate from those of the geometry of the plane.

This theory of surfaces by Gauss has been extended by Riemann to continua of any arbitrary number of dimensions and has thus paved the way for the general theory of relativity. For it was shown above that corresponding to two infinitely near space-time points there is a number ds which can be obtained by measurement with rigid measuring rods and clocks (in the case of timelike elements, indeed, with a clock alone). This quantity occurs in the mathematical theory in place of the length of the minute rods in three-dimensional geometry. The curves for which $\int ds$ has stationary values determine the paths of material points and rays of light in the gravitational field, and the "curvature" of space is dependent on the matter distributed over space (*see* RIEMANNIAN GEOMETRY).

Just as in Euclidean geometry the space concept refers to the position possibilities of rigid bodies, so in the General Theory of Relativity the space-time concept refers to the behaviour of rigid

bodies and clocks. The space-time continuum, however, differs from the space continuum in that the laws regulating the behaviour of these objects (clocks and measuring rods) depend on where they happen to be. The continuum (or the quantities that describe it) enters explicitly into the laws of nature, and conversely these properties of the continuum are determined by physical factors. The relations that connect space and time can no longer be kept distinct from physics proper. Nothing certain is known of what the properties of the space-time continuum may be as a whole. Through the general theory of relativity, however, the view that the continuum is infinite in its timelike extent but finite in its spacelike extent has gained in probability.

Time

The physical time concept answers to the time concept of the extrascientific mind. Now, the latter has its root in the time order of the experiences of the individual, and this order we must accept as something primarily given. One experiences the moment "now," or, expressed more accurately, the present sense experience (*Sinnen-Erlebnis*) combined with the recollection of (earlier) sense experiences. That is why the sense experiences seem to form a series, namely the time series indicated by "earlier" and "later." The experience series is thought of as a one-dimensional continuum. Experience series can repeat themselves and can then be recognized. They can also be repeated inexactly, wherein some events are replaced by others without the character of the repetition becoming lost for us. In this way we form the time concept as a one-dimensional frame which can be filled in by experiences in various ways. The same series of experiences answer to the same subjective time intervals.

The transition from this "subjective" time (*Ich-Zeit*) to the time concept of prescientific thought is connected with the formation of the idea that there is a real external world independent of the subject. In this sense the (objective) event is made to correspond with the subjective experience. In the same sense there is attributed to the "subjective" time of the experience a "time" of the corresponding "objective" event. In contrast with experiences, external events and their order in time claim validity for all subjects.

This process of objectification would encounter no difficulties were the time order of the experiences corresponding to a series of external events the same for all individuals. In the case of the immediate visual perceptions of our daily lives, this correspondence is exact. That is why the idea that there is an objective time order became established to an extraordinary extent. In working out the idea of an objective world of external events in greater detail, it was found necessary to make events and experiences depend on each other in a more complicated way. This was at first done by means of rules and modes of thought instinctively gained, in which the conception of space plays a particularly prominent part. This process of refinement leads ultimately to natural science.

The measurement of time is effected by means of clocks. A clock is a thing which automatically passes in succession through a (practically) equal series of events (period). The number of periods (clock time) elapsed serves as a measure of time. The meaning of this definition is at once clear if the event occurs in the immediate vicinity of the clock in space; for all observers then observe the same clock time simultaneously with the event (by means of the eye) independently of their position. Until the theory of relativity was propounded it was assumed that the conception of simultaneity had an absolute objective meaning also for events separated in space.

This assumption was demolished by the discovery of the law of propagation of light. For if the velocity of light in empty space is to be a quantity that is independent of the choice (or, respectively, of the state of motion) of the inertial system to which it is referred, no absolute meaning can be assigned to the conception of the simultaneity of events that occur at points separated by a distance in space (*see* MICHELSON-MORLEY EXPERIMENT). Rather, a special time must be allocated to every inertial system. If no coordinate system (inertial system) is used as a basis of reference there is no sense in asserting that events at different points in space occur simultaneously. It is in consequence of this that space and time are welded together into a uniform four-dimensional continuum. (A. EI.)

RECENT DEVELOPMENTS

The preceding section of this article remains essentially as it was originally written by Albert Einstein.

The more recent developments in the structure of space-time have taken three different directions. First, cosmologists have attempted to describe the properties of space-time in the large. By this is meant that instead of asking what the structure of space-time is, for instance, in the neighbourhood of a star or in the solar system or even in the neighbourhood of a galaxy, the goal is to describe the gross properties of the universe as a whole in terms of the gross geometrical structure of space-time. Second, unified field theories were developed, the aim of which was to show that not only gravitational forces, but also electromagnetic (and nuclear) forces are manifestations of the geometry of space-time. Third, modern developments in the quantum theory of the electromagnetic field suggested that a certain structure should be attributed to those portions of space-time which in the past were considered to be empty. The detailed description of this structure forms the modern quantum theory of the so-called vacuum.

A brief description of the new results must necessarily be incomplete. According to the theory of relativity, the geometrical structure of space-time determines the physical processes; hence, a detailed description of this structure would be equivalent to characterizing all the physical processes that can take place. This would entail rather more than any short discussion.

Cosmological Theories.—Briefly, here is what cosmological theories indicate about space-time. They emphasize four essential features of space-time: (1) the distribution of matter in space-time; (2) the time dependence of the geometry; (3) whether space-time is open or closed; (4) whether space-time is singly connected or multiply connected. The last two points refer to the geometry of space-time in the large. To understand the distinction implied in point (3) observe that a sphere (*q.v.*) represents a curved space that is closed, while the surface of a paraboloid (*q.v.*) is open. To appreciate the idea of multiple-connectedness in point (4), note that the surface of a sphere is called a singly connected, two-dimensional space while the surface of a doughnut (torus) is classed as a doubly connected two-dimensional space. (Roughly speaking, if the space as viewed from a higher dimensional space has one or more "holes" in it, then it is multiply connected.)

Point (1) is answered by the so-called cosmological principle, which states that on a large scale all positions in space are equivalent; irregularities are only local. Thus on a large scale the universe is homogeneous. This still tells nothing about point (2), the development of the universe in time. With this postulate there are two classes of theories. The steady-state theory assumes that the universe should be stationary; *i.e.*, its broad aspects should not change in time. The other theories assume the existence of a cosmic time that measures the evolution of the universe. The limiting case of both classes is the static universe. However, about 1930 E. Hubble at the Mount Wilson Observatory discovered that the nebulae in the observable part of the universe are receding from earth. This observation automatically rules out the possibility that space-time should be static as was originally proposed by Albert Einstein (1917). The evolving universes can be of the following kinds: (1) In the very early initial stages of the evolution, the universe was exceedingly small and contained exceedingly high densities of matter; that is to say, it has developed from a point source. (2) The universe was originally a static Einstein universe; from this stage it is now developing by expansion (Lemaître-Eddington universe). (3) The universe, originally contracted from an extremely large initial size, reached a minimum size and is expanding again. The space-time structure so described can still be open or closed; singly connected or multiply connected.

From these different theories, the second was the most commonly accepted. However, since 1940 interest in the other the-

ories revived. The point-source model (1) was invoked by George Gamow, Edward Teller (1939), and others to explain not only the origin of the universe but the generation of the elements composing the universe as well (*see* COSMOGONY; COSMOLOGY).

The steady-state theory was put forward by Hermann Bondi and T. Gold (1948) and by Fred Hoyle (1948). According to this theory the large-scale structure of space-time is independent of the position of the observer and of the time of observation. This postulate is called the "perfect cosmological principle," in contradistinction to the above-mentioned "cosmological principle" which postulates homogeneity only as far as space is concerned. However, with this assumption a difficulty arises. Notwithstanding the homogeneity in space and time, it is necessary to incorporate the observed fact that the universe is expanding and carrying matter away from the neighbourhood of any observer. Thus on the one hand an observer should see on the average the same amount of matter around him, clustered into nebulae; and on the other hand he should see these nebulae, with the matter contained in them, moving away. If this be true the thinning out of matter by expansion must be replaced by a continuous creation of matter out of nothing. This process cannot be observed per se (the amounts are too small) but it gives rise to a number of predictions of things that are observable, including the distribution of age among nebulae.

For many years there was no significant observational evidence to discriminate among the different cosmological theories. In 1960 an analysis (A. Sandage) of the ages of a number of galactic and globular clusters in terms of the relationship between their colour (red shift) and their visual magnitude suggested that the steady-state model may be inconsistent with observed data (*see* NEBULA: *Red Shifts and Expansion of the Universe*). From 1961 to 1965 two new classes of celestial objects were discovered: the quasi-stellar radio sources (quasars) and the quasi-stellar galaxies (so-called blue objects) which resemble the quasars in many optical properties, but do not emit at radio frequencies (*see* QUASI-STELLAR RADIO SOURCES). In addition, in 1965 cosmic radio-noise emission was observed. Analysis of these experimental data suggested that the actual distribution of the quasi-stellar objects is incompatible with the steady-state theory; and that the cosmic noise can be interpreted as red-shifted radiation that initially emerged from a primordial fireball out of which the universe developed. This interpretation also discriminates against the steady-state theory; however, the results were not sufficient to tell whether the universe is open or closed.

Less work has been done on the connectivity of space-time. John A. Wheeler has put forward the interesting suggestion that space-time is multiply connected, to such an extent that if it could be viewed from a higher-dimensional space it would be foamlike, riddled with holes. The "bubbles" in the foam are used in his theory as apparent sources and sinks of the electric field.

Unified Field Theories.—In the General Theory of Relativity all forces that produce acceleration are gravitational. Moreover, these gravitational forces stem from the geometry of space-time. This, however, does not mean that the only interactions described by the theory are those commonly called gravitational. In the General Theory all the usual forces (*e.g.*, electromagnetic, elastic) produce accelerations by modifying the geometry of space-time which in turn produces a gravitational field. Mathematically this arises in the following fashion: For every interaction, whether it be gravitational, electromagnetic, and so on, there is a corresponding energy-momentum tensor; and the geometry of space-time is determined by this energy-momentum tensor (*see* FORCE; ANALYSIS: *Analysis and Space*). However, the General Theory alone cannot give the laws for these tensors; *i.e.*, cannot show how the electromagnetic fields modify the geometry of space-time. The unified field theories are attempts to accomplish this as far as electromagnetic forces are concerned, conceiving these laws to be geometrical restrictions on space-time.

This modifies the geometry of space-time profoundly. It makes the geometry either higher dimensional or non-Riemannian. The modifications brought about this way are too abstract and technical to be discussed here.

An entirely different approach was proposed by Wheeler, who preserved the Riemannian geometry of space-time by retaining the source-free equation of the electromagnetic field and the Einstein equation for the gravitational field, with the electromagnetic field energy as its source (*see* GRAVITATION: *Theories of Gravitation*). However, the charges, which are usually thought of as sources of the electromagnetic field, do not appear here at all as particles, but are seen as the manifestation of the multiply connected nature of space-time.

Modern Quantum Theory of Fields.—This area of study has also left its mark on the development of space-time concepts. Quantum theory denies the possibility of the simultaneous measurement of certain quantities with arbitrary accuracy. For example, it asserts that the momentum (mass times velocity) and position of a particle cannot be measured simultaneously with arbitrary accuracy. These rules are expressed by the Heisenberg uncertainty relations (*see* UNCERTAINTY PRINCIPLE). In general, three main directions can be pursued.

1. The question can arise of how far the uncertainty relations will be reflected in efforts toward specification of space-time. First, is it possible to attach labels to points in space-time that would tell with complete accuracy what is meant by "here" and "now"? Second, even if it were possible to do this labeling locally, can the labeling be spread over the whole of space-time while preserving complete accuracy? The answers to these questions are not yet known.

2. Suppose the first question were answered in the affirmative, thus allowing use of the concept of space-time as it stands. It is immediately apparent that the uncertainty relations would affect the General Theory. For, according to the Heisenberg relations, it is not possible to measure the position and momentum of a particle simultaneously and precisely. On the other hand, if the gravitational field of the body can be measured, the General Theory permits just that. Thus, the General Theory must be modified to make it consistent with quantum theory. This can be accomplished for weak gravitational fields, with the following results. Space-time is still characterized by the $g_{\mu\nu}$ tensor (*see* above: *Effect of Relativity, Special and General*) but this $g_{\mu\nu}$ tensor cannot be known in general with perfect precision; instead, what is known is the probability that in a given physical situation it will have certain values. Thus the discussion returns to the questions raised in point 1 above.

3. If no gravitational fields are present the General Theory considers space-time to be empty and its metric to be flat. If there is any physical process going on there will be a gravitational field generated by it, and space-time will become curved. According to the modern quantum theory of fields, however, even empty space is not completely void. This empty space (called the vacuum) is endowed with potentialities. Electrons, positrons, photons, and other elementary particles can be spontaneously created there even if only to be annihilated immediately (*see* PARTICLES, ELEMENTARY). These virtual physical processes have an observable influence on such phenomena as the emission of light by actual atoms. How will the existence of these virtual processes influence the description of space-time? Is there any gravitational field associated with these processes? Does a gravitational field influence these virtual processes? It is hard to tell what the answers will be. *See* also QUANTUM MECHANICS and references to "Space-Time" in the Index.

SPAIN (ESPAÑA), a state (nominally a kingdom under the 1947 Law of Succession, see *Administration and Social Conditions*, below) occupying more than three-fourths of the second largest

peninsula in Europe (after the Scandinavian), termed IBERIA by the Greeks, HISPANIA by the Romans. Portugal, Andorra, and Gibraltar occupy the remainder of the peninsula. The Spanish provinces comprise the mainland portion of the Spanish state, the Balearic Islands, and the Canary Islands. Total area: 194,883 sq.mi. (504,748 sq.km.). Also included in the Spanish state, although they do not constitute provinces, are certain places under Spanish sovereignty along the Mediterranean coast of Morocco (Ceuta, Alhucemas, Melilla [*qq.v.*], the Chafarinas Islands, and Peñón de Vélez de la Gomera). Total area: 12.4 sq.mi. (32.1 sq.km.). The colonial possessions of Spain comprise Spanish West Africa (the two overseas provinces of Ifni and Spanish Sahara [*qq.v.*]) and Equatorial Guinea (*q.v.;* formerly Spanish Guinea, consisting of the overseas provinces of Río Muni and Fernando Po).

This article is divided into the following sections and subsections:

I. PHYSICAL GEOGRAPHY

1. General Features.—The Iberian Peninsula may be described as more continental in dimensions and more African in character than the other two great Mediterranean peninsulas, the Italian and the Greek. From Madrid, just south of which is the reputed geometrical centre of the peninsula (at Cerro de los Ángeles), the rail distances to Cádiz (424 mi.; 682 km.) on the south coast, Valencia (294 mi.; 473 km.) on the east, and Santander (302 mi.; 486 km.) on the north give some idea of the dimensions of the peninsula. Spain includes the greater portion, but it seems legitimate to discuss at some points the physical characteristics of the peninsula as a whole.

Although seven-eighths of the peninsula's borders are washed by seas, its massive form of 250,000 sq.mi. (647,500 sq.km.) is dominated by the great block of the Meseta (Spanish, Meseta Central, "central tableland") at an average elevation of 2,000–2,500 ft. (610–760 m.) above sea level. Mountain walls forming the rims of the Meseta effectively isolate the extensive interior from the coast and on the western side have provided Europe's oldest frontier, between Portugal and Spain, for more than eight centuries. Thus, the monotony of its wide central plateaus and the diversity of its peripheral mountain ranges have emphasized its continental character.

The narrow width of the Strait of Gibraltar suggests that the peninsula shares many North African affinities. The vast plateaus have their geographical counterpart in the High Plateaus of Algeria and a geological similarity with the Moroccan Meseta. The great spreads of pediments (erosional surface features associated with arid climates, termed *rañas* in southern Spain) brightly stained by the drought; the badlands of the Ebro Basin, Upper Tagus (Tejo or Tajo), and the Segura; and the relics of inland drainage deepen this similarity. The dwarf palm so characteristic of North Africa is found along the Spanish littoral as far north as Tarragona, while the pseudosteppe lands of southeast Spain have a similar cover of esparto and other plants.

But the peninsula has European characteristics also. The landscapes of the rainy northern and northwestern regions are similar to those of other Atlantic communities, such as Brittany and Ireland. Comparable customs reflect a common origin, in what has been termed the "Atlantic civilization." Much of the settlement of the Iberian Peninsula has moreover been profoundly influenced by the Christian reconquest and the 500-year struggle with Islam. It may be, however, that due to the peninsula's peculiar position and relief it has never successfully served as a bridge between North Africa and Europe. It has suffered the worst of both worlds, somewhat remote from European developments and yet not unified in one culture. Its backward look fostered regionalism and localism so that the province and its *comarca* subdivision have much geographical significance.

2. Geology.—Broadly, the geological outcrops consist of Paleozoic crystalline rocks in the western Meseta, Tertiary clays and coarser detrital deposits in the central basins, and Mesozoic folded limestones in the east and north. The Meseta, which has been tilted westward, occupies four-sevenths of the peninsula. Some of its bordering mountains represent the epicontinental margins of Secondary seas, others Secondary geosynclines. Two Tertiary tectonic depressions of contrasted evolution flank the Meseta: the Ebro trough to the north, and the Baetic Basin to the south (now deeply eroded by the bed of the Guadalquivir). A third depression is infilled by the lower valley of the Tagus and the Sado in Portugal. The Alpine systems of the Pyrenees and the central basins of the Meseta have been infilled by Tertiary and Quaternary deposits. Thus in the paleography of the peninsula, three units have been recognizable since Secondary times: the Paleozoic block of the Meseta; the epicontinental margins, especially to the east; and the geosynclines to the north and southeast.

The Meseta is a fragment only of the great Hercynian continent which extended from North Africa across Europe; it has existed as a peneplain since the close of the Carboniferous Period. It consists of Paleozoic rocks which range from Cambrian to Carboniferous. The great thicknesses of Cambrian slates in the Asturias, Galicia, Extremadura (Estremadura), and Portugal indicate relatively uniform marine conditions at the time of their deposition. Evidence of a pre-Paleozoic or Huronian mountain system is uncertain. The evidence of Caledonian orogenesis between the Cambrian and Silurian epochs is more certain, especially in the folds of the Sierra Morena. Silurian deposits reflect the folded relief with thick conglomerates and sands covering the borders of the southwestern massif and the isolated block under the Ebro trough. During the Devonian, deep geosynclinal condi-

MAJOR POLITICAL AND PHYSICAL FEATURES OF SPAIN. INSET MAP SHOWS LAND USE AND MINING SITES

tions developed over the Pyrenees and the northwest. The Lower Carboniferous was also marine, markedly detrital, and then, near the Hercynian block of northeast Spain, moderately thick in the south and southwest and very thick in the Asturias. Thus marine sediments (Dinantian) alternated with continental (Culm) facies. The Culm conglomerates witness the first Hercynian movements but in the Cantabrians (Cordillera Cantábrica) the very thick Mountain Limestones indicate that folding there was much later. The Middle Carboniferous is everywhere detrital with coal seams, discordant in the northeast, but concordant and more widespread in the north. The Upper Carboniferous is continental and discordant everywhere, indicating the effects of the Hercynian uplift.

Apart from this sequence of Paleozoic strata on the borders of the Meseta, the other characteristic is the widespread occurrence of extrusive rocks and denuded batholiths of granites. According to C. Neiva there are five important magmatic phases in the Paleozoic of Portugal, the granites resulting from the solidifying of eruptive granites of various ages. These begin with basic and end with acidic rocks. The Hercynian folds gave place to the great batholiths now exposed by erosion, especially in the Pyrenees and the centre of the northwest of the peninsula where the Paleozoic geosynclines were deepest. Everywhere the effects of Hercynian orogenesis are visible in the northwest-southeast trending Armorican folds.

The second paleogeographic unit of the peninsula, the epicontinental margins of the Meseta, reflect the long period of orogenic tranquillity during the Secondary and early Tertiary eras, when marine transgressions laid down thick, fine sediments. Three subdivisions are recognizable: the wide platform of shallow depth which bordered the Meseta from south of Oviedo to about Albacete; the shallow sedimentary basin of the northeast; and the deep geosyncline which occurs between Gibraltar and the Balearic Islands.

Oscillations of land and sea laid down the three-fold sequence of Bunter sandstones, Muschelkalk limestone, and lagoonal Keuper during the Triassic. Gentle folding, in the Jurassic and the Cretaceous, produced oscillations of sea level, the marine transgressions of the Lias, Malm, Barremian-Aptian, and Upper Cretaceous (Cenomanian, Turonian, and Senonian) alternating with the regressions of the Dogger and the Gault. The beginning of the Tertiary marks the commencement of more continental conditions and the first phases of the Alpine movements.

At the end of the Eocene, Alpine movements commenced in the Pyrenees and the Sistema Penibético (Baetic Cordillera), moving outward from the centre of the ranges in several phases according to H. Stille: Upper Eocene-Oligocene; Oligocene-Miocene; Intra Miocene (Helvetian-Tortonian), and Pliocene. During the early Tertiary (Paleocene), flysch and littoral deposits were laid down

in the two geosynclines of the Pyrenees and the sub-Baetic straits between lower Andalusia and the southern Balearic Islands. But during the Miocene all the peninsula was subjected to continental conditions except the sub-Baetic straits which were wider than before. Over the eastern Meseta unconformable beds were deposited by lakes covering Old Castile, New Castile, the Ebro trough, and smaller ones in the Badajoz and lower Tagus districts. Tertiary uplift fractured the Mesetan block, often traverse to the Hercynian alignment, as in the Cordillera Carpetovetónica (Central Cordillera), Montes de Toledo, and Sierra Morena. Since the Pliocene, the basins of the Meseta have initiated the primary courses of the main lines of drainage, followed by the Ebro, Douro (Duero), Tagus, Guadiana, and Guadalquivir rivers.

3. Physiography.—Prolonged erosion, especially since the Pontian stage, has produced typical elements of relief on the Meseta. The typical form is the tableland (*mesa*), consisting of unconformable Miocene strata, laid down by rivers (Tortonian) in brackish ponds (Sarmatian) and in marshes (Pontian). The flat, upper surface of hard limestone forms an eroded capping (*páramo*), protecting the softer, underlying marls that outcrop abruptly on the slopes (*cuestas*). The sands and clays of the lower slopes form plains (*campos, campiñas, llanuras*). Villafranchian pediments (*rañas*) form a thin veneer over the plateaus, especially in Extremadura and southern Portugal. These appear related with the highest river terraces at 330–400 ft. (100–120 m.). The other terraces are Quaternary, apparently climatic, at 200 ft. (60 m.), 100 ft. (30 m.), and 30–40 ft. (10–12 m.) above the major rivers, and related to the terminal moraines. Glaciation however was of minor importance except in the Pyrenees where it has produced glacial sculpture along 186 mi. (300 km.) of the central ranges.

Landforms.—The major surface features of the peninsula may be grouped under three broad headings: the Meseta; its borderlands; the Pyrenees (Pirineos) and Sistema Penibético, together with the troughs of the Ebro and the Guadalquivir.

The crystalline base of the Meseta provides most of the high plateau country of the peninsula, rising from 1,000 to over 3,000 ft. (300–900 m.). Tilted toward the west and southwest, the Meseta carries several of the major rivers, notably the Douro, Tagus, and Guadiana. Two major series of contrasts divide the Meseta regionally. West of a line drawn roughly through Zamora, Salamanca, and Ciudad Real are crystalline outcrops, with thin soils, and much wild country. This is most extensive in Extremadura, where plateaus of 1,100–1,500 ft. (330–460 m.) run 200 mi. (320 km.) from east to west and 90–120 mi. (145–200 km.) from north to south. Only the small Tertiary basins, notably Badajoz and La Serena, have kinder landscapes. In the eastern Meseta, Tertiary sediments, several thousands of feet thick, have been carved out by differential erosion into tablelands (*páramos*), cuestas, isolated buttes (*alcores*) and alluvial plains (*campiñas*). These are more docile landscapes, widely cultivated under cereals. The Cordillera Carpetovetónica, which stretches east-northeast to west-southwest in a series of vertebrae (Cerro de la Estrella, Gata, Peña de Francia, Gredos, and Guadarrama) at heights varying between 5,000 and 8,500 ft. (1,500–2,600 m.), shows a marked contrast on its two flanks. From the north, these block mountains generally rise gradually, but on the south they fall steeply in fault scarps toward the Tagus trough. This explains the second major feature of the Meseta. In Old Castile, the Douro shows little evidence of headward erosion above the gorges on the Portuguese frontier. In contrast, the Tagus flows through a series of troughs, facilitating more vigorous erosion along its tributaries, as seen in La Alcarria. Further differences occur in La Mancha (2,200–2,600 ft.; 670–800 m.) forming a flat tableland, backed to the south by the volcanic cones of Campo de Calatrava. The Sierra Morena (4,500–5,900 ft.; 1,370–1,800 m.) forming the southern edge of the Meseta is fretted by vigorous linear erosion and fractured along the border of the Guadalquivir Basin.

The Portuguese landforms are essentially a western annex of the Meseta, protected from the more energetic orogenic movements that affected the northern and the eastern flanks of the peninsula. Alentejo is similar to Extremadura; Beira and Trás-os-Montes are Castilian in aspect. The most individualized landforms are the folded Mesozoic cuestas of southern Algarve and Extremadura. Galicia is characterized by senile features in the interior and by the effects of youthful, coastal submergence. A vast batholith, it has been fractured into a series of north-south blocks. The Cantabrian Mountains, perhaps the most formidable barrier of the Meseta's borders, have two types of relief: Hercynian landforms in the Asturias and more plastic Mesozoic relief in the east. The Iberian Mountains (Sistema Ibérico) are less of a barrier, a complex of ancient tablelands and folded ranges such as the Sierra de la Demanda, Sierra Cebollera, Montes Universales, and Sierra de Javalambre, which rise from 5,000 to 7,600 ft. (1,500–2,300 m.). A series of step faults breaks up the eastern edge of the Meseta toward the Valencian Plain.

Peripheral to the Meseta is the deceptive symmetry of arrangement in the Ebro depression and Pyrenean ranges to the north, the Guadalquivir Basin and the Baetic ranges to the south, respectively. The Spanish Pyrenees have a three-fold sequence: a central axis of high mountains (8,000–11,000 ft.; 2,400–3,350 m.), flanked by a discontinuous depression that is followed by some of the major valleys and the outer ranges that rise to 4,000 ft. The triangular-shaped trough of the Ebro is shut off from the sea by the Catalan Mountains, composite in style of relief. The Ebro Plain differs in important respects from its Andalusian counterpart. In the southeast, the Sistema Penibético rises steeply from the coast to 5,000–11,000 ft. (1,500–3,350 m.), to culminate in the Sierra Nevada. Inland, the Penibetic trough is followed by a string of valleys and plains, bordering the lower, complex sub-Baetic ranges that lie to the northwest.

Drainage.—Runoff averages about 35% of the total precipitation in the Iberian Peninsula, but it is 20% or less over much of the Meseta. As one-third of the peninsula has less than 20 in. (500 mm.) annual rainfall, the majority of the rivers have only a modest flow, less than 700 cu.m. per sec. The Pyrenees are the most important source of water so that the outflow of the Ebro is greatest. The northern streams also have abundant flow, the Nalón, for example, having more than the Guadiana (*q.v.*) at the Portuguese frontier, with only one-twelfth of its drainage area. In the south, especially in the southeast and in the Sierra Morena, even large catchment areas dry out in summer.

The characteristic regime of much of the peninsula, especially of the interior, is the double spring and autumn maxima. The marked increase of rainfall in spring, coupled with the melting snows of the mountains, accounts for this. In addition to the summer minimum, a secondary one occurs in winter. In eastern Spain, the flow is often complicated by karstic phenomena and the maximum is, in consequence, more delayed. Regimes with a single maximum occur both on the Atlantic and on the southern Mediterranean coasts, though the volume of flow in the latter is much less. Floods are common on all the large rivers, the Ebro and Tagus (*qq.v.*) having records that compare with inundations of other European rivers. But the most disastrous floods have occurred on the east coast with its steep gradients and the dense concentrations of population, especially on the Segura, Júcar (*qq.v.*), and Turia rivers.

4. Climate.—The Iberian Peninsula, lying between latitudes 36° and 44° N, is influenced by the seasonal shift of the westerly cyclonic belt in winter and the subtropical high pressure system in summer. The winter cold is consequent on the continental dimensions and high elevation of the Meseta. In summer, drought is explained by the spread of the Azores anticyclone over the peninsula. The Pyrenees coincide approximately with the jet stream (a narrow belt of intensely strong westerly wind) of the tropopause (the zone of transition between the stratosphere and troposphere, or lower part of the atmosphere) in summer, providing an effective aerological barrier to the more temperate conditions farther north. Polar air dominates Mediterranean meteorology so that in winter the Mediterranean Sea, 3–6° C (6–10° F) warmer than the Atlantic in the same latitude, acts as a catalyst, influencing frontogenesis and cyclogenesis. Spanish weather conditions therefore reflect four climatic controls: continental, Atlantic, Mediterranean, and mountain influences.

The peripheral regions have milder conditions than the continental interior, but the Mediterranean littoral is generally warmer and drier than the Atlantic coasts. The most marked contrast is between the northwest and the southeast (Santiago 66 in. [1,680 mm.] and Almería 10 in. [250 mm.]).

The humid zone follows approximately the watershed of the north coast from Galicia (excluding southeast Galicia and Bierzo) to the Basque provinces, then along the Pyrenees to northeastern Catalonia. Elsewhere, the orographic rainfall may be high—as in the Serranía de Ronda in the south, 8 in. (200 mm.)—but it is markedly seasonal. At the other extreme, the subdesert region of Murcia and Almería is perennially dry, having less than 1.2 in. (30 mm.) for each month of the year. Between them, the greater part of Spain embraces a dry zone with less than 24 in. (610 mm.), badly distributed seasonally and irregular in amount from year to year. Rainfall is low also in the centre of the river basins, being less than 12 in. (300 mm.) in the Zamora and Salamanca districts of Old Castile and at Saragossa in the mid-Ebro Basin.

In the seasonal distribution of precipitation three systems can be distinguished. On the northwestern and southern oceanic facades, a single winter maximum is marked, related to frontal depressions of polar maritime air. Along the Mediterranean littoral from Alicante to Catalonia, an autumn maximum reflects the importance of Mediterranean fronts at this season. Spring maximum rainfall in the central part of the Meseta indicates the effects of continental conditions having dry, cold anticyclonic weather prevailing in winter but the high pressure system breaking down in spring with marked convectional rainfall. The border areas of the Meseta have double maxima of rainfall; the west has a more pronounced rainfall in spring, however, and the east in autumn.

Areas above 3,000 ft. (900 m.) cover approximately one-seventh of the peninsula, so mountain climates are significant. Apart from the high ranges of the Central Pyrenees, the Sierra Nevada, and isolated summits in the Cantabrians and Cordillera Carpetovetónica that rise above 6,500 ft. (1,900 m.) and have prolonged snow cover, the majority of the mountains lie between 3,000 and 6,250 ft. (900–1,900 m.). These have 15–60 days of snow, with moderate to heavy rainfall depending upon their orientation, local winds, etc. The peripheral mountains have lower annual ranges of temperature and 40–60 in. (1,000–1,500 mm.) of rainfall, while the interior mountains have higher ranges and only 25–40 in. (630–1,000 mm.) annually.

5. Vegetation and Soils.—The rich variety of plant associations in Spain is the consequence of the varied climates and relief. Winter cold limits the olive to south of the Cordillera Carpetovetónica, except in the Ebro Valley and in small sheltered basins in the northwest. The Guadalupe-Toledo Mountains, the borders of La Mancha, and the Sierra Nevada are also excluded. North and northwest of this true Mediterranean limit, mesophytic flora of mixed deciduous species are characteristic. Two northern zones may be distinguished: a maritime, more humid zone where the common oak is important, mingling on the higher slopes with the sweet chestnut and the beech; and a transitional interior zone where the Pyrenean and Portuguese oaks mingle with the evergreen oak. Man has introduced a number of other species, notably the maritime pine and in recent decades the blue gum, especially into Santander. The sweet chestnut (as a valued food in the past) has been greatly spread, especially in the Basque provinces; the beech has competed successfully against the fir on the higher slopes, but is excluded climatically from Galicia.

South and east of these deciduous oak zones, the peninsula was formerly widely covered with the Mediterranean climax of the holm or evergreen oak. Apart from some of the mountains of Catalonia and a few other areas, this has been largely destroyed, vast areas of the Meseta being covered with regressive associations of the mint family, especially thyme, lavender, and rosemary. The pea family is represented by the broom heaths while in the northern mountains are heather and erica heaths. The plants that occur frequently in the woodland scrub also form dominant associations, such as the various rockroses (especially *Cistus ladaniferus*), boxwood, and the kermes oak. In the more humid, siliceous soils, the cork oak covers wide areas of Cádiz and Málaga provinces, and also of northern Catalonia. Pines constitute about one-third of Spanish forests, notably the stone pine in Old Castile, the Aleppo pine in the east, and the Scotch, Corsican, and mountain pines in the mountains. The zonal sequence becomes impoverished south of the Cordillera Carpetovetónica, so that there is an upward rise of the evergreen oak climax and elimination of the colder, continental species (except in the Sierra Nevada).

Along the east coast patches of dwarf palms are common and the carob is characteristic. In the southeast, esparto and Spanish broom steppes cover extensive areas, associated with salt-tolerant species in saline tracts. In addition to drought, the cold winters of Teruel and the Ebro Valley account for the occurrence there of Spanish cedar or *sabinar* steppes. Both P. Reyes, who estimated the Spanish steppes grossly at 28,000 sq.mi. (72,500 sq.km.), and E. H. del Villar, who denied their importance, have overstated their cases. In La Mancha, Almería, Murcia, Valencia, Los Monegros, and around Valladolid are extensive steppes but their limits have been confused with the Labiatae cover.

Soils.—The soils of the peninsula have been classified by del Villar as "acid-humic" in the northwest and northern Portugal, "siallitic (sialic)" over the western half of the peninsula, and largely "calcareous" to the east. The acid-humic soils are leached, associated with humid conditions and mesophytic flora, and modified into podsolized soils by the presence of pine woods. Siallitic soils are of three broad types: the humid soils of the north found on both siliceous and calcareous rocks under mesophytic flora; the intermediate type found on the borders of Old Castile with mixed deciduous flora; and the most widespread xerosiallitic soils occurring only on siliceous rocks and in dry climates, notably in the southwest. Most of eastern Spain, the Ebro Basin, and plains of Old Castile have intermediate or dry calcareous soils. These range in colour from the bright red earths of the east coast and south, through the chestnut soils of the interior, to the tawny or gray soils of the arid southeast. In the areas where cultivation has been attempted beyond its proper limits, an extreme type of soil, *calvero*, covers at least half the surface; eroded soil caps (regoliths or loose rock fragments partly covered by soil) are discontinuous and the basic rock is conspicuous on the surface.

Saline soils are widespread in the Ebro trough, especially in Lérida and also in the southeast. Patches occur also in the Campos de Criptana and Daimiel and on a wide scale in Las Marismas of the lower Guadalquivir. The black earths of Andalusia are a legacy of the Quaternary marshes which formerly constituted the Campiña.

6. Animal Life.—Its close links with Africa give Spain more African species than exist in the other Mediterranean peninsulas while the Pyrenean barrier and extent of the country explains the number of indigenous species. There are two clearly distinguished groups of fauna. The larger one is typical of the Mediterranean region, confined to the drier eastern and southern Spain, with many African and indigenous forms. The second group associated with the central European forests is found in the north. There are also alpine forms in the higher mountains, including various deer, mountain goats, and birds such as the eagle and vulture. Indigenous to the country are a type of red deer (*Cervus elaphus hispanicus*), an ibex (*Capra pyrenaica*), a squirrel of the Sierra de Segura (*Sciurus vulgaris segurae*), a hare (*Lepus granatensis*), and a water vole (*Arvicola terrestris sapidus*). Among the native birds, the azure-winged magpie (*Cyanopolius cooki*) is abundant in central Spain and the Sierra Morena, while a partridge (*Perdix perdix hispaniensis*) lives in the Pyrenees. The red partridge is common on the steppe lands and the great bustard feeds in flocks on the Meseta cornfields.

In the Pyrenean region the fauna is similar to that of France. The chamois, Pyrenean mountain goat, squirrel, and mole are characteristic. In the Cantabrians, the fauna is mainly European in character and includes, in the Picos de Europa, the chamois and the bear. In the northwest the Galician hare, the mountain goat, and ibex are characteristic.

The Meseta and Andalusia are rich in indigenous species of moles and squirrels. Muskrat, roebuck, and wolf are also found. In the Sierra de Guadarrama there are species of lynx, genet, badger, stone marten, fox, and weasel. African species predominate in the south, and in the southeast there are peculiar species of wolf, jackal, rabbit, and squirrel. There is the Andalusian weasel and the hedgehog, as well as the Egyptian mongoose which is not found elsewhere in Europe. In the Balearic Islands there are peculiar species of rat, dormouse, and genet, but an absence of squirrels and of moles and some other insectivores. There are generally no squirrels in the Mediterranean regions of Spain. At Gibraltar is confined the Barbary ape, thought either to be indigenous or to have been imported by the Romans or Arabs.

The great variety of bird life is explained partly by the variation of relief and climate and partly by the routes of migration followed by African and Northern European species. In Andalusia alone there are more than 400 species of birds, but only 20 are resident throughout the year. It is thus a characteristic of Spain to find only a few of its many birds living there permanently.

Snakes are common, the largest being *Coelopeltis monspessalanus*, but only the viper, which is rare, is deadly to man. There are many varieties of lizard, especially in the south together with the *quelonia* tortoise, and in the mountains the salamander is found. Common freshwater fish are the trout, barbel, tench, and carp.

The insect life is also varied. In Madrid Province alone, more than 350 species of butterfly have been counted, many of them endemic as well as truly African and European species. The marked contrasts between the humid northern zone and the arid centre and east are reflected in the differing species. *See* also PORTUGAL: *Physical Geography.*

II. GEOGRAPHICAL REGIONS

The geographical position of Spain explains much of its character. Tarifa on the Strait of Gibraltar is on the same latitude as both the island of Malta and Susah (Sousse, Tunisia). Cape Roca (Cabo da Roca) in the northwest is almost on the same meridian as Valentia in southwest Ireland. Spain therefore exhibits Atlantic, West European, Mediterranean, Central European, and African affinities. It is as Celtic as France, as Roman as Italy, as German as Central Europe, and even as arabicized as North Africa. The title of the Spanish kings, *Rex Hispaniarium*, indicates, apart from the empire in the New World, that there were "Spains" within the peninsula. The usage of the Roman term *provincia* first appears in 16th-century documents. Some of the provinces mark stages in the reconquest, such as those of Aragon and Old Castile; others distinguish medieval political units such as the kingdom of Navarre, the county of Catalonia, the lordship of Santander, and the principality of the Asturias. In 1811 Napoleon imposed a framework of prefectures, based roughly on drainage basins: 52 provinces were created in 1822, modified later to 47 peninsular provinces and 2 insular provinces.

Various geographers have demarcated the regional divisions of Spain. Dantín Cereceda recognized 17 regions on the basis of the ancient tribal divisions. J. F. Unstead made a division into 22. But whatever detailed divisions are made, the essential regional lineaments are those of the peripheral and central zones and Andalusia.

1. Peripheral Regions.—*The North.*—Three elements, the Atlantic Ocean, the mountain backbone, and the mild and humid climate, distinguish the northern regions from all others. Galicia is the largest region with a northern and western coastline of nearly 375 mi. (600 km.) and a dense population of more than 2,700,000. Its structure has yielded the following units: the west coastal plateaus and rías (drowned coastal river valleys), the central tablelands of Lugo, the central depression drained by the upper Miño (Minho) and Sil, and the high mountains on the east and south to the Portuguese frontier. It is a Celtic landscape of small fields, many churches, and *castros*, or hill settlements, densely scattered. Population has focused on three main areas: on the fishing villages of Rías Bajas with their sheltered, rich fishing grounds; on the Rías Altas with their more open hinterlands of rich agricultural lands, such as Betanzos; and on the valley of the lower Minho with its vineyards and lines of communication. The chief towns are Vigo, La Coruña, and El Ferrol del Caudillo—all ports. The historic towns of Santiago, Lugo, and Orense are all inland and former ecclesiastical centres of note.

The Cantabrians form a formidable barrier 30–60 mi. (50–100 km.) wide along the north coast for about 180 mi. (300 km.). The larger eastern sector comprises the Asturias in which an interior longitudinal depression centres on Oviedo. Because of the coastal cliffs, Asturias has turned its back on the sea, to concentrate on the industrial benefits of coal mining in the Oviedo Basin and its valleys. Only at Gijón is there an important port. But at Avilés a new town has developed with modern steel mills. Pastures, apple orchards, beech forests, and maritime pines form a friendly hinterland to the industrial centres.

The East.—The eastern provinces in Catalonia, Valencia, and Murcia have more cultural unity than physical uniformity. Whereas northeast Catalonia has a humid Mediterranean climate with maize (corn) fields and beechwoods, Murcia in the south is largely steppe. The mountains behind the coastal plains range from the alpine scenery of the Eastern Pyrenees (Pirineos Orientales) to the faulted plateaus and ranges of the Iberian Mountains and to the hill and basin relief of the sub-Baetic. Harnessing of the rivers has created two important economic activities: textile manufactures in the valleys of Catalonia and irrigation in the lower valleys of the Llobregat, Ebro, Turia, Júcar, and Segura. Irrigational development explains the dense lowland concentrations of population.

Of the four Catalan provinces, Lérida belongs more properly to the Ebro Valley, and Barcelona (*q.v.*) is described separately. Gerona in the northeast comprises the trough of El Ampurdán, whose landscape of shelter belts indicates it is in the realm of the cold *tramontana* winds. The southern province of Tarragona is drier, especially in the limestone hills of the Garraf, and noted primarily for its vineyards and olive groves. Tarragona is one of the oldest cities of Spain.

South of the Ebro delta with its ricefields, the low *garrique* (heathland) vegetation of northern Castellón is replaced by a narrow coastal belt of orange groves, on which Castellón de la Plana bases its wealth. From Valencia, with its fertile *vega* (valley land), to the mouth of the Júcar is the richest *huerta* (irrigated land) in Spain, concentrating three-quarters of the provincial population on less than one-tenth of its area. Valencia is the chief manufacturing city and port. In northern Alicante there has also been a concentration of population since Arab times, but the relief is distinct. The mountains are boldly terraced for muscatels, almonds, and figs, and the enclosed basins are densely populated with much irrigation from springs.

The unity of Murcia is the Segura Basin, whose river irrigates the *vega* of Murcia City and of other towns. The relief is more open and spacious, the high plateaus of Hellín and Chinchilla forming an easy approach to Castile. To the south of the plain is Cartagena, a naval base and historic port. Off the coast is the archipelago of the Balearic Islands (*q.v.*), consisting of five inhabited islands and numerous islets.

2. Central Spain.—Stretching from the Pyrenees to the Sierra Morena in Andalusia, Castilian Spain has played a historic role in uniting the diverse regions of the Meseta. In its widest sense it has about 9,300,000 inhabitants, *i.e.*, about one-third of the total population on half of the national territory. It consists of vast plateaus, framed by mountains, none of them spectacular except the southern flank of the Cordillera Carpetovetónica, and especially the Pyrenees. Wheat lands (and in New Castile, vineyards) alternate with immense waste of xerophytic shrubs (especially in Extremadura) or steppe. Light densities of population are characteristic in Old Castile, in New Castile, and in Aragon (*see* Table). But a marked contrast exists between the numerous hamlets of Old Castile and León camouflaged in adobe brick, and the whitewashed, large agricultural villages of New Castile, many of them created by the military orders of the reconquest.

The Spanish ranges of the Pyrenees (*q.v.*) stretch 275 mi. (440 km.) from west to east. The highest summit, Pico de Aneto,

rises to 11,168 ft. (3,404 m.). Whereas the Central Pyrenees widen to nearly 80 mi. (130 km.), they are only 15–18 mi. (24–30 km.) wide in the west and 6 mi. (10 km.) in the Montes Alberes, in the east. The main transverse valleys such as the Aragon, Gállego, Cinca, and Segre isolate the communities into small natural regions. Stock rearing, timber, and hydroelectric power are the main resources.

The Iberian Mountains to the south of the Ebro Valley are much less of a barrier, despite their length of 285 mi. (460 km.) and constant width of 50–60 mi. (80–100 km.). In the central sector is a series of parallel ranges separated by the basins of Teruel and Calatayud, but in the northwest the Sierras de la Demanda and Cebollera and to the southeast the Montes Universales have higher and more impressive scenery rising to 6,200–7,500 ft. (1,900–2,300 m.).

The Ebro depression, framed by the Pyrenees and the Iberian Mountains, forms a triangle running 220 mi. (350 km.) to its apex at the foot of the Cantabrians, and 100 mi. (160 km.) along its base bordering the Catalan Mountains. Lying mostly between 600 and 1,000 ft. (180–300 m.) its relief is erosional, forming a sequence of river valleys and terraces, tablelands, scarps, and residual hills such as the Sierra de Alcubierre. Piedmonts, bordering the trough, have been dissected by the tributaries of the Ebro into a series of extensive steppes, especially on the northern side, such as La Ribera of Navarre, Las Bárdenas, Violada, Hoya de Huesca, Los Monegros, Llanos de Urgel, La Segarra, and Garrigas. They are for the most part sparsely settled, except where irrigation is being developed, as in the Lérida and Violada districts. Large villages are concentrated along the Ebro Valley at intervals of 10–15 mi. (16–25 km.). But, apart from Saragossa, the capital, towns are small, such as the historic centres of Huesca and Tudela.

La Rioja, antechamber of Aragon and famed for its vineyards on the terraces of the Ebro, leads through the Burgos corridor into Old Castile. Although Burgos is a feudal and royal city rich in architecture, the surrounding countryside is relatively poor. The basin of Old Castile extends westward for 110 mi. (180 km.), fronted by the faulted edges of the Cantabrians and mountains of León. Below them are repeated monotonously the piedmonts of Palencia and León. Southward the Tertiary basin stretches for about 140 mi. (225 km.). It continuously repeats the erosional forms of Pontian plateaus and tablelands, fronted by scarps and plains widening into the alluvial valleys of the Douro and especially its northern tributaries, the Arlanzón, Esla, and Pisuerga. The southern valleys are less well watered, smaller, but more numerous, and fray the ramp that rises almost imperceptibly to the Cordillera Carpetovetónica. This extensive area, centred in the chief city of Valladolid, is the breadbasket of Spain. To the west, however, the fertile Tertiary cover with its cereal lands is replaced by thin, schistose soils fit only for stock rearing and a poorer economy. Zamora and Salamanca, the university town, stand at the borders of these contrasted landscapes.

The Cordillera Carpetovetónica, consisting chiefly of the Sierras de Gredos and de Guadarrama, culminates in the Pico de Almanzor (8,504 ft.; 2,592 m.) and Peñalara (7,972 ft.; 2,430 m.) respectively. From the ramp of Old Castile at about 3,300 ft. (1,000 m.) the central ranges merge almost imperceptibly in places. But from the south, the Tagus trough is overlooked by these mountains rising steeply above it. Thus on the south the Cordillera forms an effective climatic limit to some plants, notably the olive. Only a few passes cross the mountains, notably Puerto de Navacerrada (5,833 ft.; 1,778 m.) and Puerto de Somosierra (4,757 ft.; 1,450 m.), and these have emphasized Madrid's nodality.

The southern Meseta is much larger than the northern counterpart and extends about 150 mi. (250 km.) from north to south and about 75 mi. (120 km.) from east to west. Its major units are the Tagus trough, the tablelands of New Castile, the mountains of Guadalupe and Toledo, and the plateaus of Extremadura. The Tagus trough consists of several basins, such as La Vera and La Sagra, while the Tagus Valley is in places narrowly incised in the bordering highlands. The irrigated *campiña* of the Río Henares (upstream from Aranjuez) and the rolling tablelands widen eastward in New Castile. Two main types of landscape are distinguishable. To the north, the headstreams of the Tagus, deeply trenched, explain the dissected scarplands of La Alcarria and Serranía de Guadalajara. Settlements follow the valleys. South and east of Ocaña is La Mancha, with the most extensive area of undissected relief and—in the Campo de San Juan—the flattest plains of the peninsula. The regional name (Arabic Al Mansha, "the dry land") explains its steppe vegetation and its disrupted courses of drainage, sometimes forming salt lakes. Nevertheless about two-thirds of La Mancha is cultivated, with vast areas of cereals and extensive vineyards, especially between Alcázar and Albacete and from the Campo de Criptana to the Río Záncara. Farther west the general altitude of 2,200–2,600 ft. (670–800 m.) decreases and merges into the thin siliceous soils and poor stock-rearing country bordering Extremadura. La Mancha, the land of Don Quixote, has large villages but the historic market towns of Cuenca and Albacete are located eccentric to the region.

To the west and northwest rise the quartzitic mountains of Toledo (5,253 ft.; 1,601 m.) and Guadalupe, through which the Guadiana has cut a defile at Pantano de Cíjara where a great dam has been sited. To the southwest the 70 volcanic cones of the Campo de Calatrava give a distinctive landscape. Westward of Ciudad Real, the plateaus of Extremadura extend about 200 mi. (330 km.) into southern Portugal and 90–120 mi. (145–200 km.) from north to south. Tilted gently to the west, at 1,000–1,600 ft. (300–500 m.), the relief is represented by three elements: the softly undulating relief of the Silurian slates, the domed mountains of granite, and the steep ridges of quartzite. Apart from the fertile plains of Mérida and Badajoz under cereals and with irrigation schemes, vast areas are covered with gum cistus and other waste, with holm woodlands grazed by pigs. In the south, the Sierra de Aracena announces the borders of the Sierra Morena, with its dry valleys and sparse settlements (except in the mining districts of Ríotinto and Almadén).

3. Andalusia.—One of the most distinctive major regions of the peninsula, Andalusia had in the 1960s a population of 6,000,000. Framed by the southern border of the Sierra Morena, the Campo de Montiel, the Murcian Steppes, and elsewhere by the sea, it is divided into two distinct sectors, the Guadalquivir Valley of Lower Andalusia, and the sub-Baetic and the Sistema Penibético of Upper Andalusia. Perhaps no other region of Western Europe has had a richer cultural heritage, dating from the mineral exploitation and town life of the Tartessians and Romans. Of the 42 major towns, 38 were Roman in origin and later intensely arabicized. Compared with the rural peasantry of Castile, hard-working and resourceful, the Andalusian labourer is traditionally urban-minded and pleasure-loving. The economic strength of Andalusia has always been the balanced interests of mountain and plain, with complementary economies; thus Seville and Granada tend to represent distinct interests.

Of the two, the Andalusian Plain is the more important, supporting about 2,750,000 people, with a high population density around Seville. Settlement is markedly nucleated, with approximately 90% of the population living in about 240 large villages and towns. Significantly, the Guadalquivir Valley is the only extensive lowland in the peninsula that penetrates deeply into the interior from the coast. Its apex strikes 200 mi. (320 km.) toward the northeast from the Gulf of Cádiz. From a width of about 100 mi. (160 km.) at its mouth, it narrows to 60 mi. (100 km.) at Seville and 6 mi. (10 km.) at Úbeda, but to the south it is flanked by two other narrow depressions followed by the valleys of the Genil and Guadiana Menor. A marine trough until the late Quaternary, the fine sediments have been carved into smoothly undulating relief, famed for its black soils. These are intensively cropped, with olives on the hill slopes. The marshes of Las Marismas and sand dunes of the Arenas Gordas are the only lands not utilized for agriculture. In Huelva, where cork forests and stock rearing are important, is a major afforestation scheme with eucalyptus forest, planted since 1940. Olive groves are very important in the other provinces; they cover 46% of the cultivated area of Jaén, 32% in Córdoba, and 26% in Seville; many have been planted since the 19th century. Vineyards are significant

in the Condado of Huelva and Montilla in Córdoba. In the Campiña, more than 80% of the nation's cotton is grown. The chief towns are Seville and Huelva (both ports), Córdoba, and Jaén.

Upper Andalusia, though slightly smaller than the plain, is the dominant physical influence, bringing heavy rainfall on its southwestern flanks, and the source of the major tributaries of the Guadalquivir. Although the mountain ranges extend structurally for 500 mi. (800 km.) from east-northeast to west-southwest and are 125 mi. (200 km.) at their maximum width, they are much less compact than the Pyrenees. At their extremities they appear more like isolated mountain ranges emerging from a tangled relief of hills, plateaus, and plains. Termed the Sistema Penibético, the ranges can be divided into three zones: the sub-Baetic Mountains which rise above the Andalusian Plain to 3,000–6,500 ft. (910–2,000 m.) in three series of ranges; the central valleys and depressions traceable for about 110 mi. (180 km.) between Antequera, Granada, and Baza; and the principal chain of Sierra Nevada. Rivers have trenched, deep valleys to the coast, and deforestation of the steep slopes has created new deltas.

In Cádiz as in the Andalusian Plain, latifundia (large landed estates) are an agrarian problem, with 65% of the province comprising estates of more than 620 ac. (250 ha.) yet representing only 1.6% of the total holdings. Family interests may form several great estates, the largest of which are under tree crops, especially olive groves. Specialized cultures such as the vineyards of Jerez de la Frontera and Málaga are in smaller holdings. Vegetables and cereals are irrigated in the intermontane basins of the Genil Valley, Arroyo de la Vega of Granada, Río de Guadix, and others. On the coast at Motril, Málaga, Torrox, Torre del Mar, and Adra sugar cane and bananas are grown. Tourism on the Costa del Sol is an important economic activity. Málaga, Granada, and Cádiz are the chief cities. (J. M. Ho.)

III. THE PEOPLE

1. Ethnic Groups.—In general, modern Spanish stock is characteristically "Mediterranean" with two divisions: Ibero-insular (short, swarthy, and dolichocephalic) and Ibero-saharan (tall, dark, and slender) (*see* IBERIANS). In spite of the continuity of the Mediterranean type from the Neolithic Period, there exist contributions of Nordic, Celtic, Eastern Mediterranean, and Dinaric ancestors. In addition the Basques (*q.v.*) present a peculiar ethnic type of obscure origin. The people of modern Spain are composed of Castilians (including Cantabrians and Andalusians), Galicians (including some Portuguese), Basques, and Catalans (together with related Valencians and Balearics). (*See* also *Archaeology* and *History: Prehistory* below, and EUROPE: *Anthropology* and *Archaeology*.)

2. Languages.—The predominant language is Castilian (Castellano), also called Spanish (Español) since the 19th century, with its dialect forms (Andalusian, Asturian, and Aragonese). It is the official and literary language of Spain. The Basque language is a mysterious survival (probably dating from the Neolithic Period) in the Western Pyrenees (Navarra) and in the Basque provinces to the west. Catalan (with its variants) is widely spoken in Catalonia (northeastern Spain), in Valencia, in the Balearic Islands, in Andorra, and in Roussillon, France; it is allied to Balearic speech and Provençal and differs from Castilian Spanish, though all these languages, including Galician, which is akin to Portuguese, are derived from Latin. (*See* further SPANISH LANGUAGE; BASQUE LANGUAGE; CATALAN; PORTUGUESE LANGUAGE.)

3. Religion.—Roman Catholicism is the established religion of Spain. Following the pronouncements of the second Vatican Council, however, the Organic Law of the State (1966) established the principle of religious liberty for non-Catholics as a legal right. Though since the 18th century the percentage of practising Catholics has been on the decline, the Catholic faith has a profound influence on the life of both the ordinary people and the more educated classes. Civil marriage is allowed only for non-Catholics. There are 11 metropolitan and 54 suffragan sees. The primate of all Spain is the archbishop of Toledo. There are about 30,000 Protestants. Jews are estimated at 5,000 and the first synagogue since their expulsion in 1492 was opened in Madrid in 1959.

The anticlerical measures of the Second Republic (1931) were reversed after the Civil War of 1936–39. On June 7, 1941, the government signed an interim agreement with the Holy See regulating procedure for appointments to the Spanish hierarchy. This was confirmed in the Concordat of Aug. 27, 1953. The dignitaries of the church subscribed to an oath of fealty to the state.

4. Customs and Culture.—Regional characteristics persist (*e.g.*, Castilian, Andalusian, Galician, Basque, and Catalan), accentuated by physical considerations such as the contrast between the wetter and drier regions, and by the varying degrees in which regions have adopted contemporary ideas. Local communities, with the town as the natural unit of society, preserve a certain vitality, weakened perhaps by authoritarian rule. By the 1960s independent social organizations, common in Catalonia, in Valencia, and in the Basque country, were becoming more active and vocal, and tending to weaken the corporative structure of a "uniform" Spanish working society. Industrialization had also created an influential upper social class of businessmen and bankers. The Catholic Church, with its great social influence, was slowly re-

sponding to Vatican pressure for social and economic reforms.

Modern ways of life are changing much that is old, though the new is but slowly accepted. Traditional customs persist; the fiesta is one of the principal features of Spanish social life, particularly in the villages, but also in the towns. Besides the religious processions (*e.g.*, Corpus Christi and those of the Virgin Mary under various dedications), the fiestas are held to celebrate saints' days and include pilgrimages, fairs, and carnivals, accompanied by fireworks and bullfighting. The *romería*, or village pilgrimage to the saint's shrine, is held mostly in summer; one of the best known is the Romeria del Rocio, held on Whitsunday at Almonte in Huelva. The *verbena* is a night fair held in cities and towns, notably in Madrid. Seville has its April fair and its Holy Week processions (La Semana Santa); Valencia has its procession on St. Joseph's Eve (March 19) in which the huge *fallas*, or carnival figures, are carried; Pamplona has its festival where young bulls are driven through the streets; Lorca has, remarkably, a carnival-type fiesta on Good Friday.

(Left) Hooded penitents (*nazarenos*) passing through the streets of Seville during a traditional Holy Week procession; (above) holiday excursion of seminarians in the countryside near Burgos in Old Castile

Bullfighting (*q.v.*) remains a national spectacle, displaying a combination of personal bravery and a special art. Various sports and athletics have become popular. Football (soccer) draws huge crowds, and the Basque game of pelota is played (professionally, as a spectacle) in the Basque country and Castile.

Spanish folk music varies greatly from province to province, as do the folk instruments. Thus, in Andalusia the guitar predominates, in Castile the fife-and-drum, in Galicia and Asturias the bagpipe. The interaction of folk and art music is long-standing and intense. It showed very vividly in the *tonadillas* that began simply as incidental songs introduced into popular plays and developed, during the 18th century, into complete musical spectacles employing a fair degree of stylized folk song. The *zarzuela* is a more elevated form of these humble musical comedies. Since the middle of the 19th century the professional urban popular music of Andalusia, called *cante flamenco*, has exerted enormous influence throughout the peninsula, not only on popular music but also on the national repertory of ballet, opera, and concert.

Handcrafts are widespread. In rural areas there are basket weaving, ceramics and clay modeling, blacksmithing, glass blowing, wood and stone carving, knitting, and lace and embroidery work. In coastal areas there is a rich heritage of the lore and crafts of maritime trade and fishing, with special celebrations connected with the sea. *See* also SPANISH LITERATURE and the section on Spain in the articles PAINTING and RENAISSANCE ARCHITECTURE. IV. ARCHAEOLOGY

The progress of Spanish archaeology is revealed by the increasing number of excavations, museums, and archaeological university posts and periodicals.

The earliest discoveries go back to the Lower Paleolithic. They consist of some implements belonging to the pebble-culture and to the Abbevillian and Acheulean industries. The majority of the beds are in the terraces of certain rivers (Manzanares) and the Cantabrian zone. Discoveries of Mousterian industry are more widespread. In the Upper Paleolithic, the peninsula entered a period of some prosperity and a relatively dense population. The Cantabrian coast, the Levante, and regions around Madrid and Lisbon are the richest areas. Remains of Perigordian and Aurignacian industry occur in the north; distribution of Gravettian is more widespread. Solutrean finds are particularly common in the Cantabrian zone, the Levante, and Catalonia. Magdalenian occurs mostly in the north, but is found sporadically in the Levante (Parpalló cave). These cultures exhibit certain original features in Spain. The most notable is the manufacture by the Spanish Solutreans of a type of barbed and tanged points, anticipating by many millennia those of the Neolithic and giving rise to intriguing problems concerning its possible relationship with the African Aterian. The centre for this variant is the Parpalló cave (Gandía), but it is found throughout the Levante, extending to the south and Portugal.

One of the most admirable achievements of the Upper Paleolithic is in the realm of art. The first known Quaternary painting (*see* ALTAMIRA CAVE) was discovered in Spain; today there are about 35 known sites, from Málaga to Santander, of naturalistic art in the so-called Franco-Cantabrian style. The wealth of wall painting contrasts with the paucity of portable art (with the exception of the Parpalló cave, which has over 5,000 engraved and painted slabs). The so-called East Spanish art, which depicts scenes in rock shelters of animals painted in a naturalistic style and more or less stylized human figures, is believed to belong to the Mesolithic. More than 60 sites are known, from the province of Lérida to that of Almería.

After the Mesolithic, the Neolithic introduced a new element—pottery. The earliest known pottery (handmade) was decorated with impressions of a *Cardium* shell; pottery with incised or relief decoration was also common. In the earliest metal-using period, a Spanish form which reached the British Isles—the bell beaker—had spread halfway across Europe. The settlements and their cemeteries (the most famous is that at Los Millares, in Almería, *c.* 2000 B.C.) offer various objects of adornment, polished stone axes, flint knives and arrowheads, etc. Copper soon appeared—one of its first forms being the dagger. Megalithic building was widespread, especially in the south, west, and the Pyrenean area; it varied from simple polygonal dolmens to complex galleries and domed tombs, of indubitably Oriental origin.

With the Bronze Age, grave goods changed with the decline in the use of stone. Daggers, which were lengthened to form swords, axes, from the flat type to the palstave, arrowheads, necklaces, diadems, bracelets, rings, and bodkins were all of metal. Pottery was plain, predominantly carinated.

The El Argar culture in the southeast is the most characteristic. The western Atlantic zone was very rich in this period because of the abundance of gold, of which there is evidence in the form of jewelry clearly related to that of the British Isles. The tin trade led to the formation between the Atlantic lands of links

which endured until Roman times. In schematic art, the last reflection of Stone Age art, there are some unusual forms of engraving (Gallegan *insculturas*).

In the Balearic Islands, the later Bronze Age presents a Cyclopean architecture with parallels in Malta, Sicily, and Sardinia. In Majorca and Minorca there are settlements, artificial burial caves, and talayots (towers of various kinds). In Minorca there are also *navetas* (graves shaped like an inverted ship) and taulas, whose purpose is unknown. (*See* BALEARIC ISLANDS: *Archaeology*.)

The end of the Bronze Age brought new invasions of Indo-European-speaking peoples, especially the Celts (about the 9th century B.C.). They introduced cremation in their enormous urnfield cemeteries. Pottery was the totally exotic Hallstatt type, or the traditional excised; there were great innovations in armour and utensils. Among the deposits, that of the Huelva estuary (8th century B.C.) is outstanding. The Celts, established in the centre and the west, continued their peculiar culture into Roman times.

On the Mediterranean coasts, the first millennium B.C. witnessed the renaissance of the indigenous people, influenced by colonization: first Phoenician, continued by the Carthaginians, on the south coast and in the island of Ibiza, then Greek, on the south coast and in the northeast (Emporion, Rhode). Many trade objects, jewels, and pottery fill the collections. Thousands of native settlements or cities show a rather rudimentary planning. The enigmatic city of Tartessos, head of a kingdom in Andalusia, gives its name to a variant of this culture. Its archaeological remains are limited to some jewelry and a few inscriptions in an archaic alphabet of eastern origins. The Iberian culture includes cities, sanctuaries, and cemeteries, and in them much stone, bronze, and ceramic plastic art. The "Lady of Elche" (4th century B.C.?) is the most representative work of this group. The animal sculpture offers clear eastern prototypes. Wheel-made pottery with geometric decoration is conspicuous. In some regions stylized plant decoration is very rich (Elche, Archena), but the most important is the human decoration which is found in the southeast and most abundantly at Liria (Valencia). It depicts scenes of war, hunting, fishing, sacrifices, dances, and domestic life. There are also numerous inscriptions in the Iberian alphabet, derived from the Tartessian.

MANSELL/ALINARI

"THE LADY OF ELCHE"

Iberian sculptured bust (probably 4th century B.C.), in the Museo del Prado

In 218 B.C. the Romans entered Spain and began the process of romanization, which was accelerated in the second half of the 1st century B.C. Indigenous elements became buried under the avalanche of foreign cultural, political, juridical, and artistic elements. Study of the evolution of pottery permits a clear chronology. In the second half of the 1st century B.C. the so-called terra sigillata began to spread, made first in Italy, then in Gaul; Spanish manufacture began at the same time. In the 3rd and 4th centuries A.D., manufacturing became more common and stamped ware predominated, continuing until the Visigothic era. A new chapter of Roman archaeology has been opened by underwater exploration; among the many remains of sunken ships are a great number of amphorae in which wine and olive oil were exported.

Roman cities sometimes rise over Iberian towns, but in many cases on the plain nearby (Liria, for example); others are founded entirely afresh (Mérida), or derive from camps (León). The peace which reigned during the first centuries of the empire scattered the population through the countryside, in innumerable villas decorated with mosaics. The cities offer great monuments: temples, theatres (that of Mérida is one of the best in the Roman world), amphitheatres (Italica, near Seville), circuses, and town walls. The same richness and perfection are shown in the aqueducts (Segovia), bridges (Alcantara), triumphal arches, and monumental tombs. In the second half of the 3rd century, with the first invasions, the cities once again enclosed themselves behind strong walls and all life was impoverished.

The spread of Christianity revealed new aspects: sarcophagi, tomb mosaics, and basilica mosaics. The number of known basilicas, showing clear African and Eastern influence, constantly grows. The last chapter of Hispanic archaeology is usually found in the invasion period and early medieval times. (L. P. G.)

V. HISTORY

A. PREHISTORY

Paleolithic.—Lower Paleolithic industries are well represented in Spain, especially in the central Meseta north and west of Madrid and in Cantabria, where conditions in the penultimate interglacial period appear to have been particularly favourable to flourishing hunting communities. The Meseta group is somewhat earlier than the Cantabrian and includes industries of Clactonian type, but in general Acheulean is the first widespread industry in Spain and is found from Cantabria to Andalusia. In the east, however, industries before the Mousterian are rare. In the southern provinces, Clactonian is well though sparsely represented; other southern stations are almost entirely Mousterian.

In the central Meseta and in Cantabria the widespread Mousterian culture is continued into a mixed Levalloisian-Micoquian. Classical Levalloisian and Tayacian are found at a number of central, southern, and eastern sites. In the east industries are French in type and compare with classical Mousterian of Charente and the Dordogne. Mousterian man is represented by bones of Neanderthal type.

In the Upper Paleolithic the Cantabrian-Biscay region formed a continuous cultural area with south-central France. While the classical Aurignacian (French Middle Aurignacian) is not represented outside the Cantabrian zone, the transition from Mousterian to Aurignacian is found not there but elsewhere. Later Aurignacian with Gravettian is well represented in southern and eastern Spain and is the earliest known industry over most of this region; it includes types which have a certain parallelism with the Capsian of North Africa and the Grimaldian of southeast France and northern Italy. Solutrean occupied Cantabria and Catalonia and extended down the east coast as far as Valencia.

Magdalenian industry is particularly well represented in Cantabria. Throughout the region typical Magdalenian carved bonework, harpoons, and animal remains attest to the temporary onset of cold conditions. Magdalenian remains are also found in Catalonia and at the important cave site of Parpalló, Gandía (Valencia). Doubtless there were scattered Magdalenians throughout most of the peninsula but their influx was not strong enough to upset the widespread late Gravettian people, who in a cultural phase known as Epigravettian remained the basic population at the end of the Upper Paleolithic, with Capsian peoples on the Levantine, and Epipaleolithic-Mesolithic Azilian and Asturian cultures in the north and west seaboards.

For the world-famous Spanish cave paintings, *see* PRIMITIVE ART.

Neolithic and Bronze Age.—After the invention of pottery, Capsian flints continued in the earliest phases of the Spanish Neolithic, which first appeared in eastern and southern Spain in coastal caves and is therefore known as the "Cave Culture." Stratification of these cave deposits is difficult, but grain cultivation and the use of querns certainly reached the Spanish Cave Culture at the same time as similar cultures in North Africa, Liguria, and southern France.

There is, however, little to separate the Neolithic and the earliest metal-using cultures, for Spain was especially rich in metal ores, and a rich copper-using culture soon developed in the southeast. This was centred in the province of Almería, where most of the material comes from megalithic passage graves, probably introduced by an invading Mediterranean people. Undoubtedly there was a pre-metal phase of the Almerian culture, but this is

difficult to define. Two habitation sites of round and oval huts have associated passage graves and have no traces of metal. One of these is El Garcel, a village of wattle and daub houses and grain storage pits. Agriculture (grain, olives, vines) was well developed, but the flint industry is still the primitive Capsian. Pottery is related to that of North Africa, and there is a little stone idol with eastern Mediterranean affinities. Some fragments of copper are, however, known in later phases.

Later village sites in Murcia Province have rectangular houses. A number of dolmen and cave burials and an extension of the Almerian culture into Andalusia also fit into this phase. In these earlier phases burial was in cists and collective round megalithic graves of dolmen type.

The richest phase of the Almerian culture (*c.* 2000–1500 B.C.) is found at Los Millares on a bank of the Andarax at the base of the Sierra Nevada, a triangular site defended by a fosse and ditch and predominantly associated with passage-grave burial. Copper becomes more abundant, used only for small objects such as earrings and pins. During this phase the Almerian culture spread into the southwest and into Portugal, and throughout "beakers" related to those of West and Central Europe are found.

The fourth phase of the Almerian culture (*c.* 1500–1000 B.C.) is fully Bronze Age and is best represented at the small prehistoric township of El Argar. Here there is a complete change in burial (to jar burial) and skull type, obviously indicating the arrival of new people. In one grave were found eight segmented faïence Egyptian beads of a type known to date to *c.* 1400 B.C.; these provided the first fixed chronological point in Iberian prehistory.

The Almerian culture can also be traced into southern Portugal, where there occur a number of passage graves of the second and third phases. In the mountain lands there is a progressive impoverishment, seen in megalithic tombs without vaulting.

The full Bronze Age in Spain was a period of retrogression except in the southeast where around El Argar on the Río de Antas a flourishing culture arose and spread throughout the southwest where it is mainly represented by naturally defensive settlement sites in Almería Province and in Murcia. Copper was still more common than bronze and many molds for metal casting were found; gold and silver were used for beads and other ornaments; metal mining was probably the chief source of wealth. A pair of pottery horns from El Oficio (Almería) suggests eastern Mediterranean connections.

This strong Bronze Age culture of El Argar flourished throughout the second half of the 2nd millennium B.C. and spread north to Catalonia, east to Alicante, south to Andalusia and Portugal; north of the Segura River it becomes less typical, especially in Catalonia; here as in other peripheral regions pottery of Neolithic Cave Culture type persists almost to the Iron Age. In the northeast in the final phases of the Bronze Age new pottery types and bronze ax heads of European type foreshadow increased contacts across the Pyrenees and the drawing of the Iberian Peninsula into the Central European Late Bronze Age cultural orbit.

Atlantic Bronze Age.—The final phases of the Bronze Age culture flourished on the Atlantic coast and in the extreme southwest. New South European and central Mediterranean influences brought to these regions new metal types, above all a notched shield (the Herzsprung shield) which is known in Cyprus and Samos and can be dated *c.* 720. No actual shields survive in southern Spain, but a number are engraved on flat rock pictures, chiefly in Extremadura. Besides shields, these rock pictures show carp's-tongue swords, molded fibulae, combs, mirrors, and wheeled chariots, all of which suggest a local invasion of a Mediterranean people introducing new metal techniques. Close cultural contact between the Atlantic seaboard and Galicia and Brittany and Ireland is particularly strong in bronze and gold work.

Iron Age.—Iron-using Celtic peoples of trans-Pyrenean Hallstatt culture invaded Spain in waves from 900 to 500 B.C. (these cannot be precisely dated). Their first phase of settlement, lasting down to 650 B.C., brought them in concentrated numbers as far south as the Ebro and penetrated lower Aragon. Villages are known, made up of rectangular clay and stone houses facing on to a simple pattern of streets. Late offshoots of this first Hallstatt phase passed to the south through Castellón, and even Almería was influenced by the early Catalonian urnfields. This phase reached the west coast (Alcácer do Sal) and Guadalquivir Valley (Carmona); also, antennae-hilted swords of a type used in the final phases of Central European Hallstatt were engraved on stones in Extremadura, and bronzes of Hallstatt type were found in the Huelva River.

A second major wave between 600 and 400 B.C. carried Hallstatt culture over the central Meseta into Lusitania and the far southwest as well as into Galicia, where in the last four centuries B.C. an evolved culture of scattered forts (*castra*) aligned itself with northern and central Portugal rather than with the west of Spain. Avienus' *Ora Maritima* speaks of Celtic tribes occupying the Meseta in the 6th century, and ancient place names ending in *-briga*, *-dunum*, and *-acum* attest to a Celtic settlement which must certainly have taken place well before the Central European Celts passed about 450 B.C. into the La Tène cultural phase, which did not reach or influence Spain.

Four main areas stand apart from the general pattern of Celtic settlement. The lands of the north coast were settled by the Cantabri (*q.v.*), Astures, and Vascones (modern Basques), who, while partly celticized, were ethnically separate from the Celtic Galicians of the west and such Celtic tribes as the Ilergetes in the east. The south coast between Gibraltar and Málaga was occupied by a mixed race of local Bronze Age peoples with a Phoenician element called Bastulo-Poeni. South Catalonia, part of Aragon, Valencia, Castellón, Granada, Jaén, and Andalusia were held by the non-Celtic Iberians (*q.v.*), a Mediterranean people with Hallstatt burial rites but of strictly unknown ethnic formation who had a written language and excellent pottery of non-Central-European derivation and were heavily influenced by Greek and Phoenician culture. Although many of their metal types were derived from the Urnfield people and their villages were very similar to those in Aragon and Catalonia, their shrines and chambered tombs were decorated with reliefs and free-standing sculpture in an exotic and highly individual style. They were masters at bronze casting and hundreds of small bronze votive statuettes provide a picture of their physical characteristics. Lastly, in the Ebro Valley and the northeastern Meseta the Iberians and Celts fused into a group of tribes known to classical authors as the Celtiberians (*see* CELTIBERIA). This mixed Celtiberian culture spread over most of east and central Spain in the century preceding the Roman conquest.

B. Early Colonization

Tartessos.—The rich mining culture of southeast and southwest Spain first became known to the classical world by the voyage of Colaeus of Samos, who sailed there *c.* 630 B.C. and opened trade with the region of Tartessos. Classical sources agree that before the Greeks discovered southern Spain the Phoenicians traded with Tartessos (according to some Greek writers Gades [Cádiz] was founded *c.* 1000 B.C.); consequently, it has been equated with the biblical land of Tarshish, to which the ships of Solomon and Hiram of Tyre made three-year round voyages. Possibly the names of Tartessos and Tarshish can be philologically connected, and there is no doubt that while biblical writers used the word "Tarshish" as a rather general geographical term for lands where minerals were mined, it was nevertheless properly regarded as being at the western end of the Mediterranean. Tartessos itself, according to Strabo, was an island city at the mouth of the Guadalquivir and was destroyed by the Carthaginians about 500 B.C.; its site was unknown in Roman times and has remained so. From the 7th century B.C. the Guadalquivir Valley was occupied by an Iberian tribe called Turdetani, a name whose root might also have some connection with *Tart*essos.

Phoenicians.—Existing archaeological evidence shows that Phoenician seaborne trade reached the estuaries and lower reaches of the Guadalquivir, Guadiana, and Tagus rivers about 600 B.C. A few metal objects in southern Spain attest to local manufacture of Phoenician objects, some of which found their way to the Celtic hill-forts on the west of the Meseta. Phoenician influence in the southeast is less marked, but there seem to have been early

contacts with the region of Valencia and also with the inland Iberians of Tutugi (Galera district, Granada), of Peal de Becerro (Jaén), and of Cástulo (Jaén). Although nothing as early as the date of Solomon and Hiram has been found, there is every likelihood that the Phoenicians obtained ores from the El Argar people long before active trade between the Phoenicians and Tartessos.

Greek Settlement.—From the mid-7th to the late 6th century B.C. Greek contact with eastern Spain was incessant. Besides the commerce with Tartessos, Greek trading settlements were founded on the east coast at Hemeroscopeion (Punta de Ifach), Mainake (possibly Málaga or Almuñécar), and the unlocalized Oinussa, Molybdana, and Heracleia by the Ionian Phocaeans. The Rhodians founded Rhode on the Golfo de Rosas in the northeast in the 7th century. After the Phocaeans founded Massilia (Marseilles) *c.* 600 B.C., this northern corner of Iberia became important; and the first permanent large Greek colony on Iberian soil was founded from Massilia at Emporion (modern Ampurias on the coast of Catalonia). Although, meanwhile, the Phocaean foundations to the south had fallen to the Carthaginians, Ampurias remained independent down to the Roman occupation and did a brisk trade with Punic Ibiza as well as with the Iberian tribes of the interior. There are considerable objects of Greek trade found in the southern and eastern regions of Spain. The cultural impact of the Phocaean Greeks upon the indigenous Celtic tribes of the north and the Iberians of the south is very great and far outweighs that of the Carthaginians.

Carthaginians.—About 520 B.C. the Phoenician settlements came under the chief Phoenician city in the west, Carthage (*q.v.*), and with them access to the mines and a recruiting ground for mercenaries. After the First Punic War (264–241 B.C.) Carthage was left with Gades and a few other coastal settlements in Spain. From 237/236 Hamilcar Barca and his successors Hasdrubal and Hannibal (*qq.v.*) extended Carthaginian rule over many tribes. Hasdrubal founded Carthago Nova (Cartagena) and accepted the Ebro as a northern frontier in a treaty with the Romans in 226/225. Hannibal's attack in 219 on Saguntum (south of the Ebro but allied to Rome) led to the Second Punic War (*see* PUNIC WARS). (WM. C.)

C. THE ROMANS

Victory in the Second Punic War (218–201 B.C.) left Rome with two embryonic Spanish provinces: Hispania Citerior, the eastern coastal strip based on Tarraco (Tarragona) and Carthago Nova; and Hispania Ulterior, comprising the southern coast and the valley of the Baetis (Guadalquivir); the two are often referred to as Hither and Farther Spain, respectively. Thereafter the task of deepening the provinces by advance inland was bitterly pursued. Year by year, with each province under its proconsul, Roman soldiers and Roman money were poured in, until Scipio Africanus' epic capture of Numantia in 133 B.C. allowed advance northward to the Durius (Douro) and westward to the middle Tagus. Administration, though usually opportunist, was not always merely oppressive or self-interested; and although annual tribute was imposed on native communities they received certain advantages—security, peace, safe communications, new opportunities of production and commerce, employment under Roman arms, and acquaintance with Roman civil law. Agriculture, viticulture, and fisheries flourished in the south and east, as the local coin types attest, even if these activities were controlled by Roman capital; trunk roads were constructed (*e.g.*, that from the Pyrenees to Carthago Nova), and coinage developed from the proceeds of the innumerable mines, of which Rome claimed the gold while leasing out the silver, lead, and (probably) copper.

When in 80–72 B.C. the Roman Quintus Sertorius used Spanish supporters against Roman political rivals, he did so as the leader of an already half-romanized army. Julius Caesar's governorship of Hispania Ulterior (61–60 B.C.) saw the frontiers extended up to the mouth of the Durius. Later, as dictator, he initiated a new colonial and municipal policy, bringing Italian settlers to Spain and granting Latin rights to certain indigenous communities. Gades became a fully fledged Roman *municipium*. Roman peace was swiftly followed by Roman political consciousness; language, religion, and public life were henceforth molded and unified by the central Roman model.

Augustus' first task was to undertake, by bloody and savage warfare, the conquest of the northwestern (Asturio-Cantabrian) corner of Spain—not complete until 19 B.C. Now, with the whole peninsula tamed, he effected its total reorganization, though the precise date (in any case earlier than 2 B.C.) is uncertain. Baetica (roughly the Guadalquivir Valley with the southern coast) became a "public" province, without regular troops, under senatorial proconsular administration; Lusitania (a new province roughly coextensive with modern Portugal south of the Durius) and Tarraconensis (comprising all the rest of the peninsula) were imperially administered under propraetors with three legions as a permanent garrison in the latter. Major regional towns or cities became centres of government and local jurisdiction. Emerita Augusta (Mérida), a pattern of Augustus' many newly founded watchdog colonies of veteran soldiers, typifies, by the wealth of its remains today, their imposing character. Colonies and full *municipia*, formed *ex hypothesi* of Roman citizens, were self-governing and subject only to citizens' taxes. Unprivileged communities were administered by the provincial governor and subject still to payment of tribute. Although Augustus was chary in extending the Roman franchise, his work for Spain was enormously beneficial and widely recognized as such. The building of roads and bridges, the encouragement of local enterprise, the unification of sentiment, and the establishment of profound peace, while raising the standard of living everywhere, were not imposed at the cost of rigid conformity. Political, religious, and financial anomalies were tolerated. Rome's principal reward consisted of the vast output (perhaps unequaled elsewhere) of gold, silver, copper, iron, tin, and lead from Spanish mines.

The Augustan model was faithfully preserved. Claudius reduced the garrison to two legions, Vespasian to one. The road complex was developed swiftly. Spanish wine, by its cheapness, and oil, by its quality, disturbed the previous pattern of world markets. Vespasian imposed stricter regulations for the control of all the principal Spanish mines, the revenue of which afterward flowed into the imperial treasury. But early in his reign he recognized a century of astonishing progress by simultaneously promoting about 350 unprivileged communities to Latin rights. Spain could not now deny the presence of the golden age, marked by security, a high and well-diversified culture, and a balanced and critical civilization, which gave Rome the younger Seneca, Lucan, Martial, Quintilian, Columella, and Pomponius Mela as literary or academic ornaments, and the emperors Trajan and Hadrian. The 3rd and 4th centuries saw initiative, if not prosperity, declining. City walls (some hastily built in the 3rd-century crises) crumbled in neglect, through excessive dependence on Rome; and when the barbarians burst the Rhine frontier in A.D. 406–407 and flooded Gaul and Spain, there could be neither resistance nor hope of recovery. (C. H. V. S.; X.)

With the irruption in 409 of the Vandals, the Suebi (Sueves), and the Alani (Alans), Spain entered on a long period of division and confusion. The Vandals and their associates, who plundered far and wide, were not numerous enough to swamp the population. When in 429 Gaiseric led the Vandals and Alani out of Spain into North Africa, his whole horde numbered only 80,000 persons, including old men, women and children, and runaway slaves. The contemporary writers Orosius and Salvian say that many subjects of the empire in Gaul and Spain preferred the barbarians to the tyranny of the imperial tax collectors. The great landowners had, moreover, almost as much to fear from the agrarian insurgents known as Bagaudae as from the barbarians. The most resistance to the barbarians came from the least romanized part, the north; the Basques were independent until 574. Spain was thrown back into its pre-Roman state of division, with the vital difference that the country now possessed the tradition of the Roman law, the municipalities, and one great organization in the Christian church (unfortunately, the barbarians were usually converted to Arian Christianity).

After the fall of the rival emperors, first Constantine, then

VISIGOTHIC LEGISLATOR

Representation of a legislator from *Leges Barbarorum*, a Visigothic collection of laws written in A.D. 793

Maximus (*qq.v.*), supported by the Roman army in Spain, the Romans enlisted the help of the Visigoths (*see* GOTHS). Ataulphus (*q.v.*), the successor of Alaric I and husband of Placidia, sister of the emperor Honorius, entered Spain in 415 but was murdered the same year. Wallia was soon elected king and continued Ataulphus' work. He crushed the Alani and drove the Vandals and Suebi into the northwest. But then he handed Spain back to the imperial officials and marched with all his people (418) into Aquitania Secunda, which had been assigned to them by Honorius.

The Romans did not give up hope of recovering Spain, even after the Visigoths (*see* below) were firmly established. In 552 Justinian took advantage of a disputed Visigothic succession to send a force which occupied much of the south coast for the Eastern Roman Empire. The Visigoths regained Corduba in 572 and Carthago *c.* 622; part of Algarve was Byzantine until 629. (X.)

D. THE VISIGOTHS

The Visigothic rulers of Aquitaine began to intervene in Hispanic affairs early in the 5th century but it was not until 494, during the reign (484–507) of Alaric II, that large-scale migration to Spain began. The migrants, who certainly did not number more than 200,000, included peasants as well as warriors and clergy and established their overlordship without serious opposition (497). In the areas where they elected to settle, the Hispano-Roman landowners (*hospites*) were compelled to surrender to the newcomers two-thirds of their cultivated land (*sortes Gothicae*), but there was no general expropriation even in Old Castile, where Visigothic settlement was densest. The political capital of the Visigothic monarchy was transferred from France to Toledo in the reign (551–567) of Athanagild.

Though the invaders were both politically weak and already highly romanized, powerful influences at first prevented any rapid assimilation to the native population. The Visigoths were followers of the Arian heresy and remained subject to their own legal codes, while the Hispano-Romans were Catholics and continued to be governed by Roman law. Intermarriage between the two races was prohibited. Instability was to be the outstanding feature of the state set up by the Visigoths in Spain. Because of the ambitious Visigothic nobility's strict insistence on the principle of elective monarchy, the crown was constantly menaced by political intrigue, and the removal of the sovereign by deposition or assassination was frequent. Leovigild (568–586)—one of the few effective Visigothic kings—finally destroyed (585) the remnant of the Germanic kingdom set up by the Suebi in northwestern Spain about 175 years before and managed to bring the ever-rebellious Basques under his control; he also dealt successfully with a Catholic rebellion against the state religion. But the next king, Reccared (586–601), was baptized a Catholic soon after his accession, and the third Council of Toledo then proclaimed the conversion of the whole kingdom (589).

The removal of the religious barrier allowed the assimilation of the two groups to progress more rapidly, and the councils of Toledo, where nobles as well as clergy were represented, now began to dominate the crown. The reign (621–631) of Swintila saw the final expulsion of the Byzantine prefecture set up in southern Spain in Athanagild's time. In the time of Sisenand (631–636), the fourth Council of Toledo completed the subjection of king and government to ecclesiastical authority. An event of great significance for the subsequent history of medieval Spain was the promulgation by Recceswinth (649–672) of the *Liber judiciorum* as the sole legal code for both peoples. This was a new compilation, drawn up by order of the king *c.* 654, in which Germanic customary law predominated over Roman legal traditions.

It is probable, however, that the extent of assimilation brought about by Reccared and Recceswinth has been somewhat exaggerated. Even after their reforms only nobles of pure Visigothic descent could be elected to the throne, and the Germanic nobility was thus encouraged to maintain its blood line up to (and after) the final fall of the monarchy.

Wamba (672–680), the last king of any stature, attempted to reorganize the decadent military institutions of his kingdom but was deposed by a trick; and the energies of the next three kings were chiefly concerned with holding their thrones against the intrigues of their political enemies. By the time of Roderick (Roderic; 710–711) the disintegration of the state was complete. Apparently as a result of an invitation from Roderick's opponents, Tarik, the Arab governor of Tangier, crossed the Strait of Gibraltar with an invading Arab and Berber army in 711. Roderick called for national unity against this grave threat, but even then the Visigothic nobles declined to abandon their suicidal partisanship. Defeatism was deliberately encouraged by some of them in the army that Roderick had assembled; in consequence it was routed by Tarik at the Battle of Guadalete, south of Medina Sidonia (July 19–26, 711), the king himself disappearing from history.

The collapse of the Visigothic monarchy in Spain followed at once. A substantial number of members of the large slave population abjured Christianity to improve their social position; most of the peasantry did likewise. The Jews, subjected to fierce persecution since the reign of Sisebut (612–621), welcomed the tolerant invaders as liberators. A number of high Visigothic nobles accepted Arab suzerainty, and the invaders speedily completed the occupation of almost the whole peninsula. Though the Arabs took one-fifth of the land for themselves the Christian communities were left with their religious and legal independence intact and were protected by Koranic law.

The social system of the Visigothic monarchy had consisted broadly of an aristocracy of nobles (*primates*) and clergy; a large class of freemen (*ingenui*) of mixed ethnic origin; and a numerous

slave class (*servi*). The *aula regia* (royal household) was made up of palace officials (*palatini*), who held the title of count by virtue of their offices. Provinces were governed by *duces* or *comites* and subdivided into areas ruled by *judices*. This stratified society without clear political ideals proved incapable of creating any sense of national cohesion during the two centuries of Visigothic rule in Spain. Though they were by no means without creative capacity in letters and the visual arts, it was as lawgivers that the Visigoths exercised their greatest influence on the history of Spain. Recceswinth's *Liber judiciorum* remained the basic legal code of Christian Spain for centuries after the disappearance of the last Visigothic king; and, by a curious paradox, memories of the feeble Visigothic state were now to prove strong enough to sustain the small Christian states of the north in their long resistance to Islamic military and cultural power. (P. E. R.)

E. Moorish Spain to 1031

During the reign in Spain of the Visigothic king Witiza (701–709) Arab forces of the caliphate (*q.v.*) had conquered northern Morocco and laid siege to Ceuta, the last remnant of the Byzantine possessions. It seems certain that Julian, the imperial count or governor of Ceuta, incited the Arab viceroy in North Africa, Musa ibn Nusair, to attack Spain, possibly by arrangement with the sons of Witiza. After a successful preliminary raid by the Berber Tarif in 710, Musa ordered his governor at Tangier, Tarik ibn Zaid, to make a descent in force. In 711 Tarik crossed with 7,000 men, mostly Berbers, and, after reinforcement by 5,000 more, awaited the advance of Roderick, Witiza's successor, near the Laguna de la Janda, south of Vejer de la Frontera. There, on July 19, Roderick was defeated and probably killed. The sons and partisans of Witiza, who had withdrawn during the battle, now joined Tarik and encouraged him to advance northward to seize Toledo, while a detached force occupied Córdoba. In June 712 Musa crossed with an army of 18,000, mostly Arabs, captured Seville and Mérida, and dispatched his son Abdul-Aziz to the southwest, before he joined Tarik at Talavera. After wintering at Toledo, he resumed his advance in 714, captured Saragossa, and made with Tarik a two-pronged expedition into León and Galicia before returning to Damascus at the caliph's command. His son Abdul-Aziz, after occupying Portugal, completed the conquest of Granada and Murcia, where the duke Theodomir (called Tudmir by the Arabs) became tributary. Other Arab forces pushed northeast into Septimania; and later governors continued to raid into Gaul, where, although defeated by Charles Martel at Poitiers in 732, they maintained an advanced base at Narbonne until its capture by Pepin III in 751.

The invaders met little opposition on the whole. The sons of Witiza and other great Visigothic families, whether converted to Islam or not, compounded by payment of tribute for extensive domains. The Jews, freed from persecution, were eager allies, and the serfs gained a measure of freedom. Conversions were on a large scale, and the Spanish converts (*muwallads*) became an active and turbulent element in the general Moorish population. The unconverted, called *mustaribs* (*mozárabes*), did not suffer much from interference and, like the Jews, formed prosperous communities in the Muslim cities. The Arabs, in spite of continuous immigration, were too few to colonize the country; they formed the administrative and military cadres, maintained by the allotment of fiefs in the region of Saragossa, the eastern and southern coasts, and the Guadalquivir Valley. The Berbers settled mainly in the centre and in mountainous regions which resembled their native land and favoured their anarchical tendencies. The Berber revolt in Morocco in 740 produced a parallel outbreak in Spain, and Berber risings, large and small, continued for the next two centuries. Among the Arabs, also, the intertribal feud between Kais (Qays) and Kalb (*see* Caliphate) was reflected in Spain, complicated by rivalries between the early immigrants (*baladis*) and the Syrian contingents (*shamis*) which came in from 741 onward. In this patchwork of racial and tribal discords, rebellion was almost endemic, and the resulting lack of unity remained a permanent characteristic of al-Andalus, as Moorish Spain was called (*see* Andalusia).

The Omayyad Dynasty.—In 755 the Omayyad prince Abd-al-Rahman ibn Mu'awiya, escaping from the massacre of his relatives in Syria, landed at Almuñécar, and with Kalbite support captured Córdoba (756). He waged pitiless warfare against internal disorder for more than 30 years and established a centralized power based upon an imperial guard of Berbers and European slaves (Slavonians). The pious Hisham I (788–796) tried to stem the expansion of the Asturian kingdom. A series of *muwallad* revolts, at Saragossa, at Toledo, at Mérida, and in Córdoba, threatened to dislodge his successor, al-Hakam I (796–822), who, however, by his implacable resolution reaffirmed the Omayyad power and laid the foundations of the material and literary culture which developed under the urbane Abd-al-Rahman II (822–852). The peace was again broken under Mohammed I (852–886) by successive *muwallad* and Berber revolts, often with Asturian support, notably those of the "Visigothic" Beni Kasi at Tudela and Saragossa, and of Omar ibn Hafsun in the Sierra de Ronda. General disintegration and civil war among and between Arabs, Berbers, and *muwallads* in all quarters forced his son 'Abdallah (888–912) to adopt a temporizing and defensive strategy.

'Abdallah's grandson Abd-al-Rahman III (912–961) by resolute and far-sighted leadership lifted the kingdom from this morass to an apogee of power, culture, and magnificence. Within ten years he mastered Ibn Hafsun (d. 917) and his sons, and in ten more he reunited Moorish Spain. He proclaimed himself caliph in 929. In spite of occasional reverses, he forced the Christian princes to pay tribute to Córdoba, now a metropolis enjoying immense reputation and prestige in all Europe. He greatly enlarged the Slavonian guard, whose officers acquired increasing power at the expense of the old Arab aristocracy. The reign of his son al-Hakam II (961–976) was no less brilliant. The weakness of Hakam's son Hisham II (976–1013) favoured the rise of a military dictator, the Arab Ibn abi-'Amir, later entitled al-Mansur (Almanzor) (981–1002), under whom, as under his son 'Abd al-Malik al-Muzaffar (1002–08), the military power of the caliphate, now recruited mainly from Morocco, was at its height. But beneath the surface the old antagonisms and social discontents were still alive. In 1009 they broke out in a political crisis which temporarily reduced Moorish Spain to chaos and from which it never fully recovered. While Slavonians and Berbers by turn occupied Córdoba and made and unmade caliphs, the rest of al-Andalus threw off all allegiance to the Omayyads and was dissected among a host of petty rulers. After Córdoba itself had been occupied by the Moroccan Arab house of Hammuda (1016–27), the last Omayyad prince was dethroned in 1031 and replaced by a republic. *See* also Abd-al-Rahman; Córdoba, Caliphate of. (H. A. R. G.; X.)

F. Christian Spain to 1479

The history of Christian Spain during the period 711–1479—a subject long distorted by religiopatriotic myths originating in the time of the Catholic Kings (Ferdinand and Isabella)—is dominated by the interplay of two opposed forces: the idea of an ultimate Christian conquest of the whole peninsula; and the inescapable fact that, historically, culturally, and economically, the Christian and Islamic peoples of Spain had become irretrievably associated with each other. The Christian will to reconquer, based partly on religious feeling, partly on the Visigothic tradition of Spanish unity, and mostly, perhaps, on economic motives, only sporadically took on a militant crusading form before the end of the 11th century. When it did so the economic consequences of the crusading spirit were often scarcely less harmful to the Christian conquerors than to the conquered Moors. Thus Ferdinand III's conquest of Andalusia in the 13th century was undertaken in a spirit of intolerance that brought permanent economic ruin to southern Spain and so severely damaged the economic prospects of the conquering state, Castile. This experience, and the very different results of the conquest of the Moorish kingdom of Valencia by the economically more educated Aragonese and Catalans, taught the Castilians prudence and the fact of the *convivencia* between Moor and Christian reasserted itself. From the middle of the 13th century to 1479 the Castilian attitude to Granada was decidedly ambivalent while Castile, Aragon, and Navarre all ac-

cepted the presence within their frontiers of substantial numbers of Islamic subjects (mudéjares) to whom royal protection was accorded.

The Kingdom of Asturias.—Before the tide of Arab and Berber invasion a number of Visigothic nobles and their retinues withdrew to the mountains of Asturias and there elected a Visigothic prince, Pelayo (*c.* 718–*c.* 737), as their king. The Berber revolt in Morocco and Spain (741) and the consequent withdrawal of the Berber garrison in Galicia led to the attachment of Galicia to the new kingdom by Alfonso I (739–757). Under Alfonso II (791–842) the Asturian capital was moved from Cangas de Onís to Oviedo. Later kings pushed forward from the mountains to the central plain and their armies operated with success far to the south. The discovery, early in the 9th century, of the supposed tomb of St. James at Padrón in Galicia and the establishment of the shrine at Santiago de Compostela made the Asturian kingdom guardian of a shrine of European significance and gave it a symbol of national unity. Alfonso III (866–910), the greatest of the Asturian kings, expanded his domains as far as Coimbra in the southwest and Burgos in the southeast. By now the situation was stable enough for his successor, García I (909–914), to move the capital from the Asturian mountains to the city of León.

The Asturian kings, like their Leonese successors, regarded themselves as direct heirs to the traditions of the fallen Visigothic monarchy; and, for this reason, the historical writings of Alfonso III's reign emphasized their obligation to undertake the reconquest of all Spain. The Asturian administration followed Toledan models as closely as circumstances permitted. Yet the organization, social and political, inherited from the Visigoths was already being changed by the immigration of a free Mozarabic peasantry from the south, while Frankish political ideas also exerted some influence on Asturian society. In general, however, it can be said that the Asturian kings handed on to the kings of León a tradition of isolation, not only from Moorish Spain but also from the rest of Christian Europe, which experience was to show could not be sustained.

The Kingdom of León.—The transfer of the Christian capital from Oviedo to León coincided with the establishment of the caliphate of Córdoba and, until the early 11th century, the balance of power in the peninsula swung strongly in favour of the Moors. That the Leonese kingdom survived at all was the result of the generalship of Ordoño II (914–924) and Ramiro II (*c.* 931–951) who, in unfavourable circumstances, secured important victories against the caliph's armies. Ramiro was, however, unable to prevent the breakaway from his kingdom of the Christian county of Castile. This district, partly recolonized by immigrants from the north, had rejected the Visigothic legal code (*Forum judicum*) in favour of Castilian customary law and showed itself hostile in other ways to the Visigothic traditions of León until, under Count Fernán González (932–970), it achieved *de facto* independence. Henceforth clashes between the innovating tendencies of Castile and the conservative traditions of León were to weaken the Christians. Ordoño III of León (951–956) acknowledged the hegemony of the caliphate, and the later attempts of Bermudo II (984–999) to assert his independence of Córdoba brought disaster on the kingdom. The armies of Ibn abi-'Amir al-Mansur occupied and destroyed León (988) and sacked Santiago de Compostela itself (997), sparing only the Apostle's tomb. Under Alfonso V (999–1028) the capital was repopulated and recovery began. However, early in the reign of Bermudo III (1028–37), a new threat to the independence of León materialized when Sancho III the Great of Navarre, after seizing the county of Castile (1028), occupied the eastern part of the Leonese kingdom. Later he entered the capital (1034) and there assumed the title of "emperor of Spain," Bermudo fleeing to Galicia. León was never wholly to recover its supremacy again.

The Rise of Catalonia and Navarre.—During the reign of Charlemagne the Franks succeeded in capturing Barcelona (801) and in driving the Moors out of the northeastern corner of the peninsula. This area, later known as the Marca Hispánica, was then occupied by a number of Visigothic counts under Frankish suzerainty. In the time of Count Guifredo (d. 898) the county of Barcelona became independent and established its hegemony over the other counties of the Marca Hispánica. Under Borrell II (*c.* 950–992) al-Mansur's armies devastated Catalonia and burned Barcelona (985); but the region recovered during the rule of Ramón Borrell (992–1018). Under Berenguer Ramón I (1018–35) it began to flourish. Because of the influence of the Franks it had already developed political and social institutions different from those of the rest of Christian Spain. The 10th century also saw the dramatic rise of the Basque kingdom of Navarre, which has little history before this period. Sancho I Garcés (905–925) added the small county of Aragon to his dominions but suffered severely at the hands of Abd-al-Rahman III's armies. A period of subordination to the caliphate followed, but Sancho II Garcés (970–*c.* 994) was spared the worst of al-Mansur's attacks and devoted himself to the political organization of his kingdom. There was, however, nothing to indicate that, under Sancho III Garcés, called "the Great" (1005–35), Navarre was to become, for a brief period, the dominant power in Christian Spain.

The Medieval Spanish Empire.—Though Sancho the Great had assumed the imperial title in León, his political ideas were hostile to the old Visigothic-Leonese tradition of peninsular unity, and his empire was largely built on a simple desire for personal aggrandizement. It included Navarre, Castile, León, Sobrarbe, and Ribagorza while Berenguer Ramón I of Barcelona became his vassal. Sancho deliberately encouraged contacts between his dominions and the rest of Christian Europe and probably did much to make the Spanish nobles aware of the feudal aspirations of their class north of the Pyrenees. He regarded his empire as his personal property and distributed it among his four sons in his will. The eldest, García IV (1035–54), inherited an enlarged Navarre. Castile was made a kingdom and given to his second son, Ferdinand; Sobrarbe and Ribagorza were united in a separate kingdom and given to another son, while the small county of Aragon was also erected into a kingdom for his fourth son, Ramiro I (1035–63). Ramiro soon incorporated Sobrarbe and Ribagorza into his new kingdom (1045), and Aragon thus began its independent history.

Sancho's will provided for the return of León to Bermudo III on his death, but this restoration was overthrown by Ferdinand I of Castile (1035–65), who speedily annexed León (1037) and reoccupied (1054) the Castilian territories given in his father's will to his eldest brother, García IV of Navarre. Ferdinand also took the imperial title and by virtue of this claimed suzerainty over his brothers. He achieved great successes against the Moors, pushing his frontiers to the Tagus in the south and the Mondego in the west and making the *taifa* (principality) kings of Badajoz, Seville, and Toledo his tributaries. On his death Ferdinand, as his father had done, divided his dominions among his sons, and there was a period of violent strife before the second of them, the brilliant Alfonso VI (1065–1109), succeeded to the whole inheritance. His reign brought great changes to Spain.

The extensive Moorish kingdom of Toledo was conquered in 1085; it had been in close political relations with Alfonso for some time before this. The conquest, involving the absorption not only of the large and culturally advanced Mozarab and Jewish communities of Toledo but also of great numbers of often highly skilled Muslim artisans and agriculturalists, considerably altered the ethnic and cultural structure of the Castilian kingdom. There was no attempt to expel the newly conquered Moorish populations, who were promised royal protection and the preservation of their religion and customs. To give formal expression to his tolerant policy, Alfonso changed the imperial title by styling himself "emperor of the two religions." It seemed for a brief time as if these changes might produce a genuine Hispano-Moorish civilization under Christian political control. Unfortunately the Almoravids' invasion of Andalusia (1086) soon removed the *taifa* kingdoms from Alfonso's control and replaced the tolerant spirit of the Spanish Moors by one of bigoted African fanaticism. Meanwhile, under the influence of his wife Constance of Burgundy, the emperor allowed French Cluniac monks, to whom the Spanish tradition of *convivencia* was wholly repugnant, to get complete control of the Spanish church. They forced Alfonso to modify his promises

of toleration toward the conquered mudéjares, compelled him to replace the old Mozarabic missal by the Roman, and contrived to have the ancient Visigothic script of Spain replaced by the Carolingian hand in use in the rest of western Europe. These innovations brought into Christian relations with the Moors something of the crusading zeal which the French monks had found deplorably lacking and ensured that medieval Spain would eventually belong much more definitely to the common political and cultural pattern of medieval Europe, though mudéjar influences long affected Spanish life and culture.

Alfonso was followed by his daughter Urraca (1109–26), widow of Count Raymond of Burgundy; her turbulent reign cannot be followed here. She was succeeded by her son, Alfonso VII (1126–57), who gave new meaning to the imperial title by extending his influence over the county of Barcelona and by forcing Ramiro II of Aragon and García V of Navarre to accept his suzerainty. The counts of Toulouse and Montpellier also accepted him as overlord and, at a ceremony at León (1135), attended by his new Christian and Moorish vassals, he assumed the title "emperor of all Spain." He also achieved resounding, if inconclusive, successes against the Moors, and the European prestige of the Spanish imperial court was recognized when Louis VII visited Alfonso at Toledo (1150). Nevertheless separatist tendencies in the peninsula secured another ominous victory when the count of Portugal, Alfonso Henriques, assumed the royal style (1140). On his death, Alfonso VII, too, divided his realm among his sons, leaving Castile to the elder, Sancho III, and León to Ferdinand II. This new partition proved the deathblow to any future revival of the imperial idea originally inherited from the Visigoths. Castile and León now remained separated for 73 years, during which the magnates began to display in a marked degree that anarchical partisanship and resistance to royal authority which were to plague Spanish life for the next three centuries. Some important successes were nevertheless achieved against the Moors during this time. In 1212 Alfonso VIII of Castile (1158–1214), Sancho's son, supported by the armies of Aragon, Navarre, and Portugal, routed the Almohad amir of Morocco, Mohammed al-Nasir, at Las Navas de Tolosa and so removed the last really serious Islamic threat to Christian hegemony in Spain. In an atmosphere of ever-mounting religious fanaticism the way was now open to the conquest of Andalusia.

The Rise of Aragon.—The Pyrenean kingdom of Aragon was brought into existence (1035) by a testamentary act of Sancho the Great of Navarre. During the rest of the 11th century it gradually encroached on Moorish territory north of the Ebro. Saragossa was captured (1118) by Alfonso I (1104–34) who, in spite of his entanglements in the internal affairs of Castile, was able to follow up this important success by occupying a large area southwest of the former Moorish capital. In 1137 Petronilla, the infant daughter of Ramiro II (accession 1134; death 1154), was betrothed to Ramón Berenguer IV, count of Barcelona, to whom Ramiro thereupon handed over the government of Aragon (1137–62). The son of the marriage, which was solemnized in 1150, Alfonso II (1162–96), formally initiated the personal union of both countries under the house of Barcelona which was to last until 1410. In 1179 an important step for the future of Aragon was taken when Alfonso made an agreement with Castile whereby the task of reconquering the Moorish kingdom of Valencia was reserved to the Aragonese crown. In exchange Aragon relinquished any claims to any other Moorish-held territory in the peninsula. During this reign, too, Aragon developed political interests north of the Pyrenees; Provence (1166) and Roussillon (1172) fell to Alfonso by inheritance, but he left Provence to his second son, Alfonso. This preoccupation with French affairs proved fatal to Alfonso's son Peter II (1196–1213) who, having added Montpellier (1204) to his dominions by marriage, became involved in the Albigensian War and was killed at the Battle of Muret (1213). His death put an end to major Aragonese political pretensions north of the Pyrenees. It is to be noted that, from 1137 to 1412, Catalonia was the dominant partner in the association of the two countries. Economically and culturally Catalonia was much in advance of isolationist and conservative Aragon, whose nobility often found itself more in sympathy with the politics of the Castilian magnates than with the bourgeois ideas of the nationalistic Catalans. Catalan was the language of the court of Aragon during the whole of this period.

BY COURTESY OF THE ARCHIVO DE LA CORONA DE ARAGON, BARCELONA

THE DONATION OF FEUDAL RIGHTS THROUGH MARRIAGE. ILLUMINATION FROM THE "LIBER FEUDORUM MAJOR," ARAGON, 1162–96

Early in the reign of Ramiro II, Navarre seceded (1134) from the Aragonese crown to which it had been united since 1076. Sancho VII of Navarre (1194–1234) tried to nominate James I of Aragon as his successor and to reunite the two kingdoms, but the Navarrese preferred Thibaut (Theobald) IV of Champagne as king (1234–53), and Navarre was thereafter ruled mostly by a succession of French princes. The little mountain kingdom nevertheless retained many of its distinctively Spanish institutions.

End of the Reconquest.—The last king of León, Alfonso IX (1188–1230), was succeeded, on his death, by his son, who was already king of Castile. Castile and León were thus finally united. The new sovereign, Ferdinand III the Saint (1217–52), at once embarked on a great series of campaigns to subdue Andalusia. These began with the capture of Córdoba (1236) and culminated in the surrender of Seville (1248). Influenced by the crusading zeal instilled into the Spanish church by the Cluniac and Cistercian orders, Ferdinand at first expelled the Moorish inhabitants of the Andalusian cities en masse but was later forced to modify his policy by the collapse of the Andalusian economy that inevitably ensued. He also assented, chiefly for financial reasons, to the establishment of the new Moorish kingdom of Granada under Castilian suzerainty. The Granadine Moors were forced to create, by hard work, a high degree of productivity in their new state in order to pay to Castile a large annual tribute, which probably became essential to the well-being of Castile's finances. This reviving tendency toward a renewal of the older tolerance toward the Moors was also reflected in the cultural field; Toledo had already become famous throughout Europe as a centre where Moorish philosophy and science were, under the stimulus of successive archbishops, made available in translation to European scholars. During the same period James I of Aragon (1213–76), Peter II's son, completed Aragon's part in the reconquest. After occupying the Balearics (1235) he captured Valencia (1238)—unlike Ferdinand III carefully preserving the agricultural economy of the Moors—and so established the final peninsular frontiers of Aragon. By these Castilian and Aragonese achievements the reconquest was, for all practical purposes, brought to an end. Both countries now gave themselves up to internal social and constitutional struggles.

Castile and León from 1252 to 1479.—The reign of the cultured Alfonso X the Wise (1252–84) was politically ill-fated. Alfonso involved himself in wars with Portugal, Aragon, and Navarre and, having got himself elected to the German throne (1257), devoted much effort and treasure to an unsuccessful attempt to make good his claims against papal opposition. At home, following the death (1275) of his eldest son Ferdinand, a constitutional struggle developed over the rival claims to the succession of Alfonso of La Cerda and of Sancho, respectively the grandson and the second son of the king. This ended in an attempt by a junta of prelates and nobles, supporters of Sancho, to depose Alfonso X (1282) and saw the beginning of an acute phase in the violent clash between the magnates and the crown which was to dominate Castilian politics for 200 years. Alfonso X's legal works, based on the renascent doctrines of Roman and canon law, laid the theoretical foundations for monarchical supremacy; but the king was too inept a politician to succeed in enforcing them. The troubled reign of Sancho IV (1284–95) was complicated by war with Aragon, which supported the succession of the house of

La Cerda; and Castile did not emerge from continuous civil strife until the end of the minority of Sancho's grandson Alfonso XI (1312–50). This Alfonso, aided by the armies of the autonomous municipalities (*concejos*), sternly repressed the magnates and succeeded in establishing a measure of absolutism which found expression in the legal and political reforms promulgated at Alcalá de Henares (1348). He also took up arms successfully against a threat from Morocco, defeating the invaders at Río Salado (1340).

The trend toward strong central government would probably have continued under his son Pedro the Cruel (1350–69) without major trouble, had not Alfonso left a number of powerful bastard sons to contest his legitimate heir's inheritance. The eldest, Henry of Trastámara, posing as the defender of the magnates against royal attempts to limit their ancient privileges, began a struggle which lasted about 19 years to seize his half-brother's throne. Meanwhile Aragonese designs on Murcia—Castile's only outlet to the Mediterranean—and Castilian ambitions in western Aragon plunged the two countries into a ferocious war (1356–66) which became even more embittered when Peter IV of Aragon espoused the Trastámaran cause in Castile. It was not, however, until France intervened actively in support of Peter IV and Henry of Trastámara that Pedro of Castile's victories in Aragon were checked. Both France and England believed that the support of the powerful Castilian fleet might prove decisive in settling the outcome of the Hundred Years' War. Pedro's alliance with England (1362) therefore led to the dispatch of the *compagnies*, the veteran French mercenaries, to Castile, financed by France and the pope (1365). Pedro fled to Gascony and secured the military intervention of Edward the Black Prince, who routed Henry's supporters at Nájera (1367). Pedro was restored but quarreled with his English ally, who then began negotiations with Aragon, Navarre, and Portugal for a quadripartite partition of Castile. In 1369 Henry of Trastámara, again with French help, defeated and killed the Castilian king at Montiel and finally gained full control of the kingdom (1371).

To counteract this French success, John of Gaunt, duke of Lancaster (*q.v.*), married Pedro's daughter and heiress Constance (1371) and thus became pretender to the Castilian throne. He was, however, unable to invade Castile during the reign of his rival Henry II (1369–79), who succeeded in consolidating his position against strong loyalist opposition. For several decades to come a close political and military alliance with France dominated Castilian foreign policy, and Castilian sea power menaced the English south coast. Especially notable was the attack of 1377, in which combined French and Castilian fleets, led by Admiral Fernán Sánchez de Tovar, ravaged the ports from Plymouth to Folkestone, and that of 1380 when they burned Gravesend and threatened London. In spite of the conservative and class-conscious ideas of the Trastámaran monarchy, the constant wars in which they were involved compelled Henry and his son John I (1379–90) repeatedly to seek financial aid from the representatives of the municipalities in the Castilian *Cortes*, who thus secured considerable control over the government. John brought military and financial ruin to his kingdom, partly because of new Lancastrian attempts to conquer Castile and partly because of his own ambitions to add Portugal to his crown. His crushing defeat by the Portuguese at Aljubarrota (1385) was followed by the landing of John of Gaunt in Galicia with a large army (1386). French reinforcements and John of Gaunt's military ineptitude, however, saved the Trastámaran dynasty and the dynastic dispute was finally settled (1388) by the marriage of Catherine of Lancaster, Pedro's granddaughter, to John I's heir, Henry III (1390–1406). Violent outbreaks against the Jews marked Henry's accession, leading to mass forced conversions destined to have a tremendous impact on Castilian culture and society. In Henry's short reign the crown reverted with success to the policies of Alfonso XI and Pedro and reduced the magnates to order by stern measures. The reign of John II (1406–54) saw a continuance of the political disintegration of Castile as a result of a renewal of the struggle of the magnates with the crown. Civil war was now frequently accompanied by armed Aragonese and Navarrese interventions. John, a politically inept lover of the arts, left the government in the hands of his able favourite, Álvaro de Luna. Luna's power was not broken until 1453, when the king, acceding to the demands of the nobles and of the queen, ordered his execution.

Under the impotent Henry IV (1454–74) the Trastámaran dynasty reached its lowest ebb. Civil strife continued unabated and was now accompanied by a collapse of the moral standards of the court. The king had married Joan (Juana) of Portugal (1455), but their daughter and heiress, also called Joan, was alleged to be the child of an adulterous relationship of the queen's. Opponents of the court accordingly favoured the adoption of the king's sister Isabella (Isabel) as heiress to the throne. Joan's marriage to Alfonso V of Portugal and his active support of her claims led, on Henry's death, to five years of civil war before Isabella triumphed and was acknowledged to be queen of Castile (Isabella I, 1474–1504) by the peace of Trujillo (1479). Ten years before she had married Ferdinand, son and heir of John II of Aragon. Thus, on John II's death (also in 1479), the crowns of Castile and Aragon became associated though not yet formally united. The 15th century had so far been an age of political, economic, and moral decay in Castile where the economy remained pastoral and where agriculture and industry had failed to develop, causing credit to be obtainable only from Jewish and *converso* ("New Christian") moneylenders. There was nothing to hint, in 1474, that the central kingdom would, within a few years, become the heart of a world state.

Aragon and Catalonia, 1276–1479.—The conquest of Valencia having ended Aragonese participation in the reconquest, it became necessary for the eastern kingdom to expand outside the peninsula if it was to avoid becoming subordinate to the hegemony of Castile. Under Peter III (1276–85) Aragon therefore began political and military intervention in Italy. As husband of Constance, daughter of the emperor Frederick II's bastard son Manfred (*see* SICILY), Peter accepted the throne of Sicily and promised to free his new subjects from the rule of Charles of Anjou. In pursuit of this aim Aragonese troops and Catalan ships secured substantial successes against French military power and papal diplomacy and made Aragon a major factor in Italian politics (*see* SICILIAN VESPERS). Papal pressure on Peter III's sons Alfonso III (1285–91) and James II (1291–1327) resulted in Aragonese undertakings to abandon Sicily; but these were not accepted by the Sicilians, and James's brother Frederick (Fadrique) was eventually recognized as king of the island of Sicily for life (*see* FREDERICK III). James also secured the grant of Sardinia to Aragon as a papal fief (1297), though the island was not completely subjugated until the 15th century. Aragonese power in the Mediterranean, which went hand-in-hand with Catalan industrial growth, was further strengthened by the activities of the Catalan Company in Asia Minor and Greece, which eventually brought about the establishment of the Catalan duchy of Athens, first under Sicilian and then under Aragonese suzerainty (*see* ALMOGÁVARES). The Aragonese dynasty in Sicily remained closely associated with the Aragonese crown, and both countries were united when Martin I of Aragon (1395–1410) succeeded his son Martin I of Sicily in 1409. The reign of Alfonso V (1416–58) saw a further dramatic extension of Aragonese power in Italy when, after a long struggle, Alfonso finally became the undisputed ruler of the kingdom of Naples (1443) and transferred his capital there.

These events reacted unfavourably on the political situation in the parent kingdom, where Aragonese and Catalan particularism grew apace and reached its climax under John II (1458–79), when Catalonia was in revolt against the crown for 11 years. The discontent of the Catalans dated back to the compromise of Caspe (1412), which had placed Alfonso V's father, the Trastámaran prince Ferdinand I (1412–16), on the Aragonese throne when the male line of the house of Barcelona had become extinct. Since 1164, when Alfonso II, already count of Barcelona, succeeded his mother as ruler of Aragon, Catalonia had been the dominant partner in the Aragonese union. Now the Catalans feared, with some reason, that the Castilian dynasty would favour Aragonese interests at their expense.

The preoccupation of successive kings with Italian affairs weakened the crown at home. In 1283 the nobles and some mu-

nicipalities of Aragon formed an *unión* and extorted from Peter III a General Privilege granting them special privileges and immunities. These were increased substantially by Alfonso III in 1287 and remained in force throughout the reigns of James II and Alfonso IV (1327–36). But in 1348 Peter IV (1336–87), who had strong absolutist leanings, routed the army of the *unión* at Epila and put an end to an intolerable constitutional situation. Peter's reign represents something of a break with the general policy of Aragon during this period. Having annexed the possessions of the Majorcan crown, *i.e.*, the Balearic Islands and Roussillon (1343–44), he challenged the peninsular hegemony of Castile (1356); but, in the ten years' war which followed, a large part of his kingdom was overrun and occupied by the armies of King Pedro of Castile. He saved himself by joining in the French effort to dethrone his Castilian rival and replace him by Henry of Trastámara. Henry promised to cede the whole of eastern Castile to Aragon in exchange for Aragonese support but declined to fulfil his promise when he had secured the Castilian throne. Long years of negotiation for an Anglo-Aragonese alliance against Castile followed, during which Peter IV sought to play off French and English interests in the peninsula for his own ends without finally committing himself to either side. In the last years of his reign the common problems with which the schism in the papacy faced the peninsular kingdoms led him to try to form a peninsular bloc that would be neutral in both religious and military affairs; but French pressure prevented the success of this far-sighted plan. Peter's son John I (1387–95), elder brother and predecessor of Martin I, left the conduct of diplomacy largely to his French wife Yolande de Bar, and Aragonese foreign policy became largely subservient to that of France. The accession of a Castilian prince to the Aragonese throne as Ferdinand I in 1412 had already foreshadowed the union of the two largest peninsular states, and this was made certain in 1469, during the reign of Ferdinand I's second son John II, when Ferdinand, the heir to the throne (born 1452), married the Castilian heiress Isabella (born 1451). The same year which saw Isabella undisputed ruler of Castile (1479) brought her husband to the Aragonese throne as Ferdinand II. The destinies of the two countries were thereafter bound together.

Medieval Institutions: Asturias, León, Castile.—The Asturo-Leonese kingdom inherited from the Visigoths the principle of elective monarchy; but in practice its sovereigns were always chosen from the same family. By the 11th century primogeniture was accepted, though the elective tradition was never formally abandoned. In accordance with their declared policy, the first Asturian kings reestablished at Oviedo the pattern of civil administration which had existed at the Visigothic capital, Toledo. Outlying regions were governed by *comites* in the king's name, and the officers of the royal household were the direct successors of the Visigothic *palatini*. The steward (*maiordomus*) and the standard-bearer (*armiger regis* or *dapifer*) eventually emerged as the chief civil and military officers of the court. By the 13th century the governorship of the larger provinces was usually held by an *adelantado*, who exercised regional military and judicial authority on behalf of the king. In some areas similar duties were carried out by the *merino mayor*. The *merino menor*, who was appointed by either of these two officers, acted as their deputy in matters of criminal jurisdiction reserved to the crown (*voz de rey*). The traditional military organization of the country was overhauled by John I of Castile in 1383 when, following French practice, a constable aided by two marshals took over the duties previously performed in the king's name by his *alférez*. The office of admiral of Castile was created by Ferdinand III. The *cancellarius* rarely appears before the 12th century. By the time of Alfonso X, however, the chancellor was recognized to be the chief civil officer of the household. The *cancillería* (chancery), like the court itself, remained ambulatory until the end of the medieval period. The employment by the king of a privy seal (*sello de la poridad*), independent of the chancery and held in the custody of its own *canciller*, was well established by the end of the 13th century. As elsewhere in Europe the privy seal was evidently used by Alfonso XI and King Pedro to further the direct control of the king over the government since, in the political reaction brought about by the accession of Henry of Trastámara, attempts were made to restrict its use. The treasury, whose officials were largely Jewish, was headed by the *almojarife mayor*, later known as the *tesorero mayor*. King Pedro created several *contadores reales* to supervise the work of local tax collectors.

In theory feudalism did not exist in Castile and León. Vassalage was not tenurial, and lands were not held for military service. The *ricoshombres*, the highest class of nobles in the medieval Iberian kingdoms, held their *honores* (estates), at least theoretically, on life tenure only. In practice, however, feudal grants did occur and from the 10th century onward the magnates attempted to usurp feudal rights for themselves. The *ricoshombres* also possessed *señoríos* (seigneurial lands), often reconquered Moorish territory given to them, with its populations, as a reward for their services. The term *ricohombre* (literally "rich man," but actually reflecting an idea of power rather than of riches) first appears in the *fueros* (laws) of Miranda de Arga, in Navarre (1162), and of Santarém in Portugal (1179). The *Siete Partidas*, the great corpus of law compiled under Alfonso X of Castile and León, describes the *ricoshombres* as the equivalent of counts and barons in other lands. Medieval Spanish writers regard as the distinctive feature of this class, which was noble by lineage, its members' right to enlist men under their private banners and to retain nobles of the second class as vassals. The *ricoshombres* regarded themselves as the natural advisers of the king and were, until the 14th century, ex officio members of the royal council. From their ranks were chosen the governors of the provinces and the military commanders. The status of the Castilian *ricoshombres* was, however, not unassailable. The king could—and sometimes did—deprive them of all their possessions. The right to coin was not granted to them; royal officers could, in theory, enter their territories to deal with certain classes of crime; a limited right of appeal from their courts to the royal courts existed—at least in name. This underlying dependence of the magnates on the crown's goodwill was largely responsible for the continual struggle of the Castilian and Leonese *ricoshombres* to keep the crown weak and to resist all centralizing and absolutist tendencies. The lesser nobles (*infanzones* and *hijos d'algo*) could be vassals of the crown or of a lord. The free peasants paid tribute for permission to till the soil either to the king on royal lands (*realengos*) or to a lord on seigneurial lands. On the *behetrías* the peasants were semifree, having the theoretical right to change their lord at will. This institution was chiefly found in those areas of Castile and León proper which had been repopulated by Mozarabic immigration during the reconquest. The serfs (*solariegos*) were chiefly found on the lands of the magnates, of the military orders, and of the church (*abadengos*). The status of the mudéjares (Muslims living under Christian protection) varied according to political conditions and to locality. The Jewish communities in the towns (*aljamas*) enjoyed royal protection until the end of the 14th century, when an outburst of popular fanaticism led to great massacres of Jews in Seville, Córdoba, Toledo, and other cities (1391) and Jewish communal life was irreparably damaged.

The most notable institution of medieval Castile was the semiautonomous municipality (*concejo*) comprising a town (*villa*) and its surrounding *comarca*. The rise of the *concejos* dates from the 11th century, and they were largely brought into being by the need to attract settlers, by special privileges, to newly reconquered areas. This was achieved by the royal grant of a franchise (*fuero*) giving the *concejo* in perpetuity a large measure of control over its own affairs and its own legal code. The *concejos* raised their own militia and formed military associations with each other (*hermandades*) in defense of their interests. They were invaluable allies of the crown in its struggles with the nobles, particularly during the 14th century, when their deputies (*procuradores*) to the Castilian parliament (*Cortes*) dominated that body. The appearance of the third estate in the *Cortes* dates from the end of the 12th century.

In the later Middle Ages the king depended on the vote of the *procuradores* for the grant of financial aid (*servicio*) necessary to cover civil and military expenditure. The heavy costs of the wars of Henry II and John I increased the dependence of the king

on the third estate. John I was forced to meet the severe criticisms of his policy voiced by the *procuradores* by creating the royal council (1386). At the beginning four representatives of each estate were appointed to the new body, and the king delegated to it (theoretically at least) many of his powers. In the 15th century the *concejos* themselves fell victims to the growth of the royal power and had to accept royal officials known as *corregidores*. A hint of impending decay had already appeared during the reign of Henry III (1390–1406) when, against the wishes of the *Cortes*, the king succeeded in making permanent the *alcabala*, a highly unpopular sales tax of one-tenth, which then became one of the main sources of royal revenue.

Medieval Institutions: Aragon, Catalonia, Valencia.—In spite of their union under the Aragonese crown, these three regions retained their own separate institutions and parliaments. There was a strong tendency toward feudalism in Aragon from the beginning, and grants of fiefs for military service were frequent. After the union with Catalonia, where feudalism was fully developed, the Aragonese nobility intensified its efforts to obtain full feudal rights. The smaller municipalities (*universidades*) were, until the 15th century, less important than in Castile because of the dominant position of Saragossa, Barcelona, and Valencia respectively in the parliamentary representation of the popular arm. The Aragonese nobility consisted of four classes, *ricoshombres de natura*, *ricoshombres de la mesnada* (created by James I), *caballeros*, and *infanzones*. These, like the representatives of the *universidades*, attended parliamentary sessions by right.

The situation of the *ricoshombres* in Aragon was much more secure than that of those in Castile. They formed a separate estate in the Aragonese *Cortes* and had absolute power over their serfs and vassals. In Aragon the *ricoshombres de natura* claimed to be descended from the original reconquerors of the kingdom. The *ricoshombres de la mesnada* were particularly attached to the royal household. In Catalonia there were three classes of magnates (*comtes*, *vescomtes*, and *valvassors*). The Aragonese *Cortes*, which consisted of four estates (*brazos*) because of the separate representation of the greater and lesser nobles, was governed by complicated rules of procedure. Redress preceded supply, and unanimity was in theory required for the approval of any measure. The *Cortes* also claimed the right to declare war. The most important political office in the country was that of the *justicia mayor*. He was arbitrator between king and nobles or people when disputes arose with the crown, and his decisions were virtually final. A permanent parliamentary commission (*diputación del reyno*) existed to deal with finance, observance of the *fueros*, and matters pertaining to the peace of the realm. The organization of the Catalan and Valencian *corts* was somewhat similar, though the former asserted a right to control all legislation. A *diputació general* in Catalonia performed functions like those of the Aragonese permanent parliamentary commission. In spite of the many restrictions on their powers it has been suggested that the Aragonese kings had greater *de facto* authority than the kings of Castile. The appointment of the *justicia* was made by the crown, and only the crown could initiate legislation. Evidence of the growth of the royal bureaucracy was the creation, in the 14th century, of the office of *maestre racional* to supervise all aspects of public finance throughout the Aragonese crown's territories.

A peculiar feature of Aragonese administration was the absence of intermediate authorities between the central government and purely local officials. In Catalonia, land belonging to the king was ruled on his behalf by the *veguers*, with subordinates known as *sots-veguers* or *batlles*; both were crown appointments. The importance of Barcelona gave that city a dominant place in the life of Catalonia. It was ruled by the *consell de cent* though, in practice, this body's authority was normally delegated to a small *consell* of five persons with whom were associated the *veguer* and the *batlle*. Catalan law was based on the *Usatges* (*c.* 1060), the oldest written feudal code. The kingdom of Valencia was governed by the constitution (*Furs*) granted to it by James I in 1239. There were wide variations in the conditions of the unprivileged classes under the Aragonese crown. The legal and economic position of the Catalan serfs (*pagesos de remença*) was worse than that of serfs anywhere else in the peninsula. On the other hand the mudéjares were comparatively well treated in Aragon proper where, until the 15th century, crown and nobles appreciated their economic importance and allowed them freedom of worship and their own tribunals. The Jews, vassals of the king, were favourably treated until the 15th century when, as in Castile, their position rapidly deteriorated. (P. E. R.)

G. The Catholic Kings

The Union of Aragon and Castile.—When Ferdinand II (*q.v.*; 1479–1516, also Ferdinand V of Castile from 1474) succeeded to the crown of Aragon in 1479, the union of Aragon and Castile was finally achieved. Ferdinand and Isabella ruled jointly in both kingdoms and were known as the *Reyes Católicos* ("Catholic Kings"). It was, however, a union of crowns and not of kingdoms. In size, institutions, traditions, and, partly, even in language, the two kingdoms differed greatly. Within the kingdom of Aragon (*q.v.*), Aragon and Valencia each had about 270,000 inhabitants of whom some 20% and more than 30%, respectively, were Moors and Moriscos (*q.v.*; Moors officially converted to Christianity). Catalonia had about 300,000 inhabitants. In each part the powers of the crown were severely limited. The barons ruled their estates like kings, dispensing arbitrary justice over their peasants. In Catalonia they had the right to wage private war. In Aragon, anyone arrested by order of the king could put himself under the jurisdiction of the *justicia*, who held his office for life and was therefore independent of the king's pleasure. It was this highest judge of the kingdom who crowned the kneeling king with the formula, "We who are as good as you swear to you who are no better than we, to accept you as our king and sovereign lord, provided you accept all our liberties and laws; but if not, not." Barcelona, in the later Middle Ages the capital city of a flourishing commercial and territorial empire in the Mediterranean, had declined owing to Italian competition and the ravages of ten years of civil war (1462–72); however, it did retain its privileges and autonomy.

Castile, too, was a poor country. Much of its soil was arid and its agriculture was backward. The armed shepherds of the powerful sheep-owners' guild, the Mesta, drove their flocks over

BY COURTESY OF THE MUSEO DEL PRADO

Ferdinand II, kneeling at left, and Isabella, kneeling at right, were given the title "Catholic Kings" by Pope Innocent VIII

hundreds of miles, from summer to winter pastures, spoiling much cultivated land. Despite the violent hostility of the landowners, the government upheld the Mesta's privileges, since the Mesta paid generously for them, and was supported by the merchants who exported the raw wool to the cloth industry of Flanders. The power of the Mesta, and the harm it did, increased in the 16th century. The impoverished Spanish peasant was unable to buy the manufactures of his urban industries, and thus the Castilian towns remained small and their industries underdeveloped, compared with those of Italy and the Netherlands. But Castile was a large country, with a population of more than 4,500,000. Despite its poverty it was much more powerful and had, potentially, much greater resources than Aragon. The Catholic Kings determined to restore the power of the crown in Castile. Once this was achieved, the liberties of the smaller kingdoms would become a relatively minor problem. (For the details of this achievement *see* ISABELLA I.)

There was also a remarkable development in the administrative machinery of Castile. The old royal council, a council of great nobles advising the king, was transformed into a bureaucratic body for the execution of royal policy, staffed by a prelate, three nobles, and eight or nine lawyers. These lawyers, mostly drawn from the poor hidalgo class (lower nobility), were entirely dependent on the royal will and became willing instruments of a more efficient and powerful central government. The Catholic Kings also set up a Council of Finance (1480, but not fully developed until much later), the Council of the Hermandad (*q.v.;* 1476–98), the Council of the Inquisition (1483), and the Council of the Orders of Knighthood (for the administration of the vast property and patronage of the Orders of Santiago, Calatrava, and Alcántara), and they reorganized the Council of Aragon. Charles V and Philip II were later to continue this work and to add further Councils, notably those of the Indies (1524) and of Italy (1558).

The Spanish Inquisition.—With its large Moorish and Jewish populations, Spain was the only multiracial and multireligious country in Western Europe and much of the individual development of Spanish civilization, in religion, literature, art, and architecture, during the later Middle Ages, was due to this fact. The Jews had served Spain and its monarchs well, providing an active commercial class and an educated elite for many administrative posts. But, inevitably, their wealth had created jealousy, and their heterodoxy hatred, in a population which traditionally saw itself as the defender of Christianity against the infidel. The Catholic Kings, ever good tacticians, profited from this feeling. In 1478 they first obtained a papal bull from Sixtus IV setting up the Inquisition (*q.v.*) to deal with the alleged evil influence of the Jews and *conversos* (converted Jews). Since the Spanish Inquisition was constituted as a royal court, all appointments were made by the crown. Too late, Sixtus IV realized the enormous ecclesiastical powers which he had given away and the moral dangers inherent in an institution whose proceedings were secret and which did not allow appeals to Rome.

With its army of lay familiars, who were exempt from normal jurisdiction and who acted both as bodyguards and as informers to the inquisitors, and with its combination of civil and ecclesiastical powers, the Spanish Inquisition became a formidable weapon in the armoury of royal absolutism. Yet the number of those whom it actually tried and condemned secretly has often been greatly exaggerated. Many good Catholics in Spain opposed its introduction, and the Neapolitans and the Milanese (who prided themselves on their Catholicism and who were supported by the popes) later successfully resisted the attempts by their Spanish rulers to impose the Spanish Inquisition on them (*see* below). Even in Spain itself, only its sumptuous autos-da-fé (*see* AUTO-DA-FÉ) seem to have been popular, not the institution itself.

The first inquisitor general, Tomás de Torquemada (*q.v.*), himself from a *converso* family, at once started a propaganda campaign against the Jews. In 1492, he persuaded the Catholic Kings to expel all Jews who refused to be baptized. Isabella and most of her contemporaries looked upon this expulsion of about 170,000 of her subjects as a pious duty. At the moment when Spain needed all her economic resources to sustain her new European position and her overseas empire (*see* below), Ferdinand and Isabella deprived Spain of its economically most active citizens and laid it open to exploitation by German and Italian financiers.

Conquest of Granada.—The Moorish question was of a different order, for the Moors still ruled their independent kingdom of Granada. The Catholic Kings had to concentrate all their military resources and call on the enthusiastic support of the Castilians to conquer the kingdom in a long and arduous campaign, which ended with the capture of Granada, the capital, in 1492. In this campaign Gonzalo de Córdoba (*q.v.*), the "Great Captain," developed the tactics, training, and organization which made Spanish infantry almost unbeatable for 150 years. The Moors were granted generous terms and religious freedom. But, against the advice of the saintly Hernando de Talavera, archbishop of Granada, who was trying to convert the Moors by precept and education, the queen's confessor, Francisco (later Cardinal) Jiménez de Cisneros (*q.v.*), introduced forced mass conversions. The Moors rebelled (1499–1500) and, after their renewed defeat, they were given the choice of conversion or expulsion (1502). Though many chose conversion, the problem now became virtually insoluble. There were never enough Arab-speaking priests, nor money for education, to make outward conversion a religious reality. The Moriscos remained an alien community, suspicious of, and suspect to, the Old Christians.

Moreover, almost for the first time in history, the two shores of the western straits of the Mediterranean were now under separate and hostile political control. The African Moors raided the Spanish coasts and often received help from the Moriscos. Isabella and Jiménez drew the logical conclusion that North Africa must be conquered. After the queen's death (1504), and largely thanks to the energy of Jiménez, the Spaniards captured Oran and some other ports (1505–10). Then Ferdinand called off the campaign.

Acquisition of Naples.—Ferdinand's foreign policy was dominated by the traditional Aragonese rivalry with France along the Pyrenees and in Italy. Aragon still held Sicily and Sardinia from the much more extensive, medieval Aragonese empire. French intervention in Italy, from 1494, gave Ferdinand his chance. Through his own Machiavellian diplomacy and through the generalship of Gonzalo de Córdoba, he acquired the kingdom of Naples (1503). For the first time the union of Aragon and Castile had shown its power, and Spain now rivaled France as the most powerful state in Europe. Ferdinand had carefully arranged the marriages of his children to strengthen his diplomatic position against France. The unexpected deaths of the two eldest and their children, however, left the succession of Castile after Isabella's death to the third, Joan ("the Mad"), and her husband, Philip the Handsome of Habsburg (*qq.v.*), ruler of the Burgundian Netherlands. As Philip I of Castile, he was supported by a large section of the nobility and forced Ferdinand to recognize his claims. But he died in 1506 and Ferdinand was left as sole ruler. Ferdinand's last great success was the annexation of the Spanish part of the small Pyrenees kingdom of Navarre in 1512.

H. THE HOUSE OF AUSTRIA

Charles I.—Ferdinand died on Jan. 23, 1516, and the crowns of the Spanish kingdoms now devolved on his grandson, Charles I (1516–56; *see* CHARLES V, Holy Roman Emperor), the ruler of the Netherlands and heir to the Austrian Habsburg dominions. This new union had not been planned in Spain and, at first, it was deeply resented. Cardinal Jiménez, the regent until Charles's arrival in Spain, had to battle against the old antagonisms between nobles and towns which were flaring up again when the magnates tried to regain their old power. Although the court at Brussels had been very careful to hold its hand, the Spaniards accused the Netherlanders of greed and place-hunting. When Charles arrived in Spain in September 1517, his supporters were already disillusioned and the country was apprehensive of the rule of a foreigner. Charles himself, young, ugly, and inexperienced, speak-

ing no Spanish and surrounded by Burgundian councillors and courtiers, did not initially make a good impression. The *Cortes* of Castile, Aragon, and Catalonia granted his financial demands but attached to them much pointed advice and criticism.

The Comunero Movement.—On June 28, 1519, Charles was elected Holy Roman Emperor as Charles V and prepared to go to Germany. His chancellor, Mercurino Gattinara, summoned the Castilian *Cortes* to Santiago de Compostela (April 1520) to demand more money, even though the former grant had not yet expired. The towns immediately made difficulties. The Toledans refused to appear; the others demanded the discussion of grievances before supply. By a mixture of bribery and concessions, the government finally induced a majority of the delegates (who had transferred from Santiago to Corunna) to vote the new grant. As Charles set sail (May 20, 1520) the Castilian revolution had already begun.

The towns, led by Toledo, formed a league and set up a revolutionary government. This *Comunero* movement spread rapidly through Castile, and the nobles did nothing to check it. They had not forgiven Charles his foreign councillors, his bestowal of the archbishopric of Toledo on a young Burgundian, Guillaume de Croy, and the appointment of Adrian of Utrecht (later Pope Adrian VI) as regent. Only when the more radical and popular elements in the towns were gaining control of the *Comunero* movement and were spreading it to the nobles' estates did the nobles combine and defeat the *Comunero* army at Villalar (April 23, 1521).

The power of the monarchy was thus restored in Castile, never to be seriously shaken again under the Habsburg kings. The towns kept much of their autonomy; but royal control in the towns was safeguarded by the appointment of royal officials, the *corregidors.* The *Cortes* continued to function, but they now willingly voted the taxes the government asked for, and the king granted or ignored their petitions as he saw fit. The nobles had won the civil war, but they could no longer break their alliance with the monarchy. The monarchy, now that it could manage the *Cortes* and afford a standing army, was the stronger partner. But when, in 1538, Charles V proposed a tax from which the nobles should not be exempt, there were immediate rumblings of revolt. Charles had to give way; but he never summoned the nobility again to the meetings of the *Cortes.* The monarchy had thus won its political victory in Castile only at the cost of letting the nobility contract out of the financial obligations of the state and the empire. The rising burden of taxes fell, therefore, on those least able to bear them, and on the only classes whose activities and investments could have developed the Castilian economy.

The Nobility.—The traditions of the grandees and hidalgos, formed in the centuries of struggle against the Moors, made them even more averse to economic activities than the rest of the European nobility. They invested their money in land, without however improving agriculture, and preferred careers in the army, the church, and the civil service to the ignoble occupations of commerce. In the long run, the economic weakness of Spain, aggravated by its social traditions and its system of taxation, proved a serious handicap in Spain's struggle with her western European rivals. After Villalar, however, the Spanish nobility had come to accept Charles V. His championship of Catholic Christianity against the Muslim Turks and the German heretics appealed to their own traditions of Christian warfare against the Moors. While Charles kept the grandees out of the central government of Spain itself, he had many prizes to offer, in military commands, provincial governorships, and even viceroyalties in Italy and Spanish America. The hidalgos, trained as lawyers at Salamanca, or as theologians at Alcalá de Henares, could look forward to dazzling careers in the king's councils and in the Spanish church. The Spanish upper classes were beginning to accept and enjoy their monarch's position as the greatest ruler in Europe.

Charles V's Foreign Policy.—Spain as a result, however, became involved in interminable wars. The necessity of defending southern Italy from the Turks brought Charles V's empire into collision with the Ottoman Empire and turned into a struggle for the control of the central Mediterranean. Ferdinand's failure to complete the conquest of North Africa now brought a bitter revenge. The corsair leader Khair ed-Din, known as Barbarossa (*q.v.*), had made himself master of Algiers (1529) and acknowledged the suzerainty of the sultan of Istanbul. Thus the purely local problem of the Moorish raids on the Spanish south coast became merged into the much more formidable struggle with the Ottoman Empire. In 1535 Charles captured Tunis; but in 1541 he failed against Algiers. At the end of his reign, the balance of the two great naval powers in the Mediterranean, the Turkish and the Spanish, was still even.

The rival Aragonese and Angevin claims to Naples also brought conflict with France, with whom Charles fought four wars. His armies conquered Milan and reduced most of the still independent Italian states to Spanish satellites (*see* NAPLES, KINGDOM OF; ITALY: *History*). As an increasing part of the burden of these wars fell on Spain, and especially on Castile, so Charles V's empire in Europe became gradually transformed into a Spanish and Castilian empire. In the last half of his reign, Spaniards and Hispano-Italians monopolized all high positions in the empire south of the Alps and began to appear in Germany and the Netherlands.

Spain in the New World.—In 1492 Columbus discovered the West Indies and, in the next half century, the Spaniards conquered huge empires in America (*see* LATIN AMERICA: *Colonial Period*) and made their first settlements in the Far East. From the beginning there were disputes with the Portuguese, who were pioneering the sea route to the East Indies around Africa and were conquering their own colonial empire. The Catholic Kings obtained a series of papal bulls (1493) from the Spanish pope, Alexander VI, and as a result concluded the Treaty of Tordesillas (*q.v.*) with Portugal (1494) to settle their respective claims. THE CORONATION OF THE EMPEROR CHARLES V

Charles V was crowned Holy Roman emperor by Pope Clement VII at Bologna in 1530. A small portion of the coronation procession is shown above in part of an engraving by N. Hogenberg, Antwerp, 1632; the pope and the emperor are seen beneath the canopy

of an imaginary line 370 leagues to the west of the Cape Verde Islands in the Atlantic was assigned to Spain; everything east to Portugal. The rest of Europe saw no reason to accept the pope's decision, and the result was constant and brutal warfare in the overseas colonies, even when the European governments were officially at peace.

Colonial Policy.—Unlike the other European colonists of that age, the Spaniards were vitally concerned with the moral problems of the conquest, conversion, and government of heathen peoples. If the great majority of the *conquistadores* ruthlessly pursued gold and power, they took with them the Dominican friars, who set themselves to convert and educate the American Indians. The Dominican Bartolomé de las Casas (*q.v.*) fought long battles to modify at least the greatest evils of colonial exploitation. His debates with the theologian Juan Ginés de Sepúlveda and the writings of Francisco de Vitoria (*q.v.*) provide the first systematic discussions of the moral and legal problems of conquest and colonial rule. Their importance lay in their effects on Spanish colonial legislation. The *Leyes Nuevas* (New Laws of the Indies) of 1542 were based largely on the arguments of Las Casas. By about the middle of Charles V's reign, the crown had managed to transform the robber empires of the *conquistadores* into relatively settled colonies whose administration was controlled from Spain.

Trade and Commerce.—The crown insisted that all trade with the colonies should be carried on through Seville and that it should be reserved for Castilians. It was closely regulated by the Casa de Contratación (1503), the house of trade, in Seville. That city itself rapidly became one of the greatest trading centres in Europe, and its population rose, from 25,000 in 1517, to 90,000 in 1594. Yet Castile was unable to supply all the manufactures which the colonists demanded and for which they paid in solid gold and silver. Castile had to import these goods itself and the Castilian monopoly of trade with Spanish America only had the effect of giving the whole of Europe the chance to compete on equal terms for the Spanish trade with the emperor's non-Castilian subjects. In both Mexico and Peru, silver mining became a major industry and rapidly increasing quantities of silver were shipped to Spain, partly as the crown's right to one-fifth (*quinto real*) but, more important, as payment for imports. The average annual quantities rose rapidly from about 1,000,000 pesos in the five-year period 1526–30, to 5,000,000 in 1541–45, and then to the peak of more than 35,000,000 in 1591–95. Prices, especially of agricultural produce, had started to rise in Spain, as in the rest of Europe, long before American silver was imported in considerable quantities. But whatever the ultimate causes of the price revolution of the 16th century, there can be little doubt that American silver greatly aggravated the inflation in Spain in the second half of the 16th century. Very little of this silver seems to have been invested in economic production. Most of it was used to pay for Spanish imports, for the Spanish armies abroad, and to satisfy the Spanish government's German and Italian creditors. Thus Spain, with all the treasure of the New World at its command, remained a poor country.

Philip II.—When Charles V abdicated his various lands (1555–56), Philip II (*q.v.*; 1556–98) succeeded to all his father's dominions except Germany. His empire in Europe, now without the imperial title, was still only a loose union of independent states recognizing the same head. Philip, a great traditionalist, was not the man to inspire his different subjects with a new unifying idea, though he improved the central administration of his empire by the creation of the Council of Italy (1558). But his own Castilian upbringing and preferences increased the tendency toward transforming the empire into a Castilian empire. Moreover the intellectual atmosphere in Spain itself had changed, from the freer and more liberal days of Charles V, when the country was open to the influence of Erasmus and of reforming ideas. All thought of reconciliation with the Protestants had now died. The influence of St. Teresa, and of St. Ignatius Loyola (*qq.v.*), the founder of the Society of Jesus, and, above all, of its new king, Philip II, made Spain the intellectual, as well as the financial and military, spearhead of the Counter-Reformation.

After another inconclusive war with France, Philip concluded the Peace of Câteau-Cambrésis (1559), which confirmed Spanish hegemony in Italy and left the frontiers of the Netherlands intact. He had inherited a debt of some 20,000,000 ducats and, in 1557, his government declared a moratorium on its debts. He still had a major naval war with the Turks on his hands and there were many problems in Spain itself awaiting solution. For the next 20 years Spain remained on the defensive in Western Europe.

The Moriscos.—The most immediate problem was that of the Moriscos of Granada. The attempt to christianize and assimilate them had proceeded much too slowly. The ineptitude and mutual wrangling of the different Spanish authorities in Granada, and the king's own rigid view of religion, drove the Moriscos into a rebellion which was put down only after a long and ferocious campaign (1568–70). At the end of it the Moriscos of Granada were deported, in small groups, to different parts of Castile and settled among the Old Christian population in a last attempt to achieve assimilation. In the absence of systematic education, and in the face of the hostility of the Christian population, this attempt was also doomed to failure.

Portugal and Aragon.—There remained the question of the complete unification of the Iberian Peninsula. In the case of Portugal, Philip's opportunity came when his nephew, King Sebastian of Portugal, in an ill-prepared crusade in Morocco lost his life and a great Portuguese army at the battle of Alcazarquivir (1578). During the short reign (1578–80) of Sebastian's old uncle, the Cardinal King Henry, Philip carefully prepared his ground in Portugal by intrigue and bribery. Nevertheless when Henry died, it was still necessary for Philip to make good his own claims by conquering Portugal in 1580. Philip respected the laws and privileges of his new subjects and left them to administer their own colonial empire. But the union increased, rather than diminished, the old hostility between the Castilians and the Portuguese. When an opportunity arose, in the 17th century, the Portuguese were quick to reassert their independence.

Philip II's last action in the peninsula was against Aragon. It was precipitated by a court intrigue which led to the flight (1590) of the king's secretary, Antonio Pérez (*q.v.*), to Aragon. Since Pérez was unlikely to be convicted in the *justicia's* court there, the king demanded his transfer to the court of the Inquisition. The populace of Saragossa rioted, freed Pérez, and killed the king's special representative (1591). To the Aragonese, it meant the defense of their liberties; to Philip it meant open rebellion. A Castilian army marched into Aragon (1591) and Philip made a number of constitutional changes. The *justicia* was, from now on, removable at royal pleasure; the viceroy could be a Castilian, and majority voting was substituted for the principle of unanimity in the Aragonese *Cortes*. These changes gave the crown the ultimate power of decision in Aragon but preserved the kingdom's autonomy.

Lepanto.—In the Mediterranean the Spanish fleet was inferior to that of the Turks and Philip had to remain on the defensive, even when the Turks were besieging Malta (1565). Their failure to capture the island from the Knights of St. John marked the end of their great offensive. Six years later, the combined Spanish, Venetian, and papal fleets—in alliance the numerical equals of the Turks—virtually annihilated the Turkish fleet at Lepanto (*q.v.*; 1571). The strategic effects of this great victory were negligible. Its moral effects were immense. It confirmed the Spaniards in their chosen role of champions of Christendom and explains much of their continued willingness to support their king's religious and imperial policies, even in the face of ruinous costs and mounting disasters. After Lepanto, however, it became clear that the stalemate in the Mediterranean could not be broken. In 1580 Spain signed a truce with the Porte (Turkish government).

The Armada.—From about 1580 the Spanish government became convinced that the rebellion (1568–1609) and heresy in the Netherlands (*see* NETHERLANDS, THE: *History*) could not be crushed as long as the rebels received help from England and France. Philip began to give financial aid to the League, the ultra-Catholic party in France. From 1586 he began to prepare the invasion of England. The Armada (*q.v.*) which set sail from Lisbon

in May 1588 numbered 130 ships and nearly 30,000 men, bravely commanded by the duque de Medina Sidonia. But it had been set an impossible task: that of convoying the army of Alessandro Farnese (*q.v.*), duke of Parma, from the Netherlands to England, in the face of a better armed English fleet and without control of a single deepwater Channel port. The defeat of the Armada was inevitable, but not dishonourable.

Spanish intervention in France from 1590 was equally doomed to failure. The duke of Parma, with his Spanish veterans, won great tactical victories. But Spain failed to prevent the succession of Henry of Navarre as Henry IV of France and the collapse of its ally, the League, when Henry became a Catholic (1593). Spain had gambled its own prosperity and the American treasure on establishing its hegemony in Western Europe, and with it the decisive victory of the Catholic Church over the Protestants, and had failed. Shortly before his death, Philip II concluded the Treaty of Vervins (1598) with France, which substantially reestablished the position of 1559. Yet, if Spain had failed in its highest ambitions, at the end of the 16th century it was still the greatest power in Europe. It had brought Christianity to millions and Protestantism had been contained, though not defeated. Spanish monks and mystics had given Catholicism a new content, and the theologians and jurists had created the basis of international law. Spanish literature and art were only now entering their greatest period. Morally and economically there were dark sides to the picture; but to the Spaniards the 16th and early 17th centuries have always been their golden century. (H. G. Ko.)

From the death of Philip II in 1598 to the accession of the house of Bourbon to the Spanish throne in 1700, that is to say during the reigns of Philip III, Philip IV, and Charles II, Spain experienced a period of serious decline, which is often referred to as the decadence of the 17th century. It was not until the last years of Charles II that a very gradual improvement took place.

Philip III.—The reign of Philip II's son, Philip III (*q.v.;* 1598–1621) saw the landed aristocracy established in power, and the rule of the *validos,* or royal favourites; first, to 1618, of the duque de Lerma (*q.v.*) and afterward of Lerma's son, the duque de Uceda. In foreign affairs, the monarchy followed a peaceful policy, ending the war with England by the Treaty of London (1604) and concluding the Twelve Years' Truce with the United Provinces (1609). It also sought to maintain its hegemony in Europe by relying on the influence of dynastic ties with other reigning families. After the assassination (1610) of Henry IV of France friendly relations were established with the French. However, schemes to aid the Balkan peoples under Turkish rule, and the problems arising in Italy, notably Spanish rivalry with Venice, which resulted in 1618 in the famous "conspiracy of Venice," an alleged Spanish plot to overthrow the Venetian Republic, compelled Spain to keep considerable forces in the Mediterranean. To meet the danger from North Africa, Philip formed an alliance with the kings of Cuco, in the Atlas Mountains; the resulting split in the Berber Kingdoms well suited Spanish policy.

This peaceful foreign policy gave an opportunity to the Spanish monarchy to try and strengthen the internal unity of the country by expelling the Moriscos (1609–14). About 300,000 were driven from Spain, well over half of whom were from the kingdoms of Valencia and of Aragon. The expulsion, however, seriously weakened the Spanish economy and brought financial ruin to the middle classes of Valencia and Aragon. They lost not only the interest but also the capital which they had advanced to the landowning Spanish aristocracy, for the latter had depended on the Moriscos for source of labour and for the dues which the Moriscos paid as vassals. On the other hand, internal unity was threatened by the beginnings of the breakdown of the union of the realm which the Catholic Kings had begun by binding the autonomous kingdoms together. In the lands of Aragon, especially Catalonia, the first indications could be seen of the regional discontent that was to lead to revolution in 1640.

Economic Depression.—Signs of an economic crisis, marking the change from the expansion of the 16th century to the depression of the 17th, are reflected in Cervantes' *Don Quixote,* the first part of which appeared in 1605. The first important monetary inflation occurred, prices rose slightly, and trade declined, despite the fact that in 1608 Spanish exports to the Indies reached a peak of 45,000 tons in a single year. By 1610 the depression was under way, a change experienced in Spain a quarter of a century before the rest of Europe, due to the fact that Spain alone received precious metals direct from Spanish America. In an attempt to solve the financial difficulties, Philip III resorted to the issue of copper currency (*vellón*). The first measure of this kind had already been taken in 1599, and was extended in 1602 and 1603. In 1617 the gap between income (5,375,000 ducats) and expenditure (8,235,000) forced the king to seek permission from the *Cortes* to issue enough copper coinage to make a profit of 600,000 ducats. The *Cortes* acceded to this request only on condition that no more *vellón* currency would be issued for at least 20 years. Nevertheless, the king resorted to a new currency debasement shortly before his death in 1621. The economic and financial crisis accentuated the social divisions within Spain, with, on the one hand, a privileged minority identifiable with the landowning aristocracy, and the mass of the poor on the other. This division explains most social ills of the time, notably begging, encouraged by the indiscriminate charity of the church; roguery (*la picardía*), which inspired much memorable literature; and banditry, particularly in the mountainous parts of Catalonia.

Philip IV.—Under Philip IV (*q.v.*; 1621–65), the eldest son of Philip III, the decline of Spain became more marked. Philip's reign in fact proved to be one of the most dramatic periods of Spanish history. Like his father, Philip relied upon favourites, the conde-duque de Olivares and Luis de Haro (*qq.v.*) and relinquished the exercise of power to the aristocracy, who governed by a system of executive councils. In 1621 Olivares renewed the war with the Dutch, the treaty of 1609 having just expired, and this move coincided with the extension of operations in the Thirty Years' War (*q.v.*), with which Spain had been involved since 1618, from Bohemia to the Palatinate and the Rhine.

Olivares' Foreign Policy.—From the very beginning Olivares planned a most ambitious policy designed to impose an Austro-

Spanish hegemony in Europe, in an attempt to recreate the empire of Charles V. The early victories of the Spanish armies at Fleurus (1625) and Breda (1625) were countered by the diplomatic success of the French minister, the duc de Richelieu, in provoking the Wars of the Valtelline (1624–26) and of the Mantuan succession (1628–31), which broke the Austro-Spanish control of northern Italy. In 1634 Spain gained its last spectacular victory of the Thirty Years' War at Nördlingen, for in the following year France intervened directly in the war, which then completely changed its character, particularly after the internal rebellions of 1640 in Catalonia and Portugal (*see* below) laid these territories open to French intrigue. The defeat of the Spanish forces by the French at Rocroi (1643) and at Lens (1648) forced Spain to recognize the independence of the United Province at the Treaty of Münster (January 1648). Eleven years later the Treaty of the Pyrenees (1659) with France deprived Spain of Roussillon and part of Cerdagne on the Pyrenean frontier, and parts of Flanders.

Catalonia.—The increasing financial needs of the crown compelled Olivares to try and forge the group of autonomous kingdoms, brought under one rule by the Catholic Kings, into a centralized state. His plan brought into the open two incompatible forces: on the one hand the system of *fueros*, or local privileges (especially in the kingdom of Aragon and above all in Catalonia); and on the other the attempt of the absolute monarchy to concentrate all power in the hands of the sovereign. Olivares clashed openly in 1626 with the Catalan and Aragonese *Cortes* over his policy of more centralized control of arms and money, and from then until the outbreak of war with France in 1635 the crisis revolved around the ambitions of Olivares and the opposition of the Barcelona *bourgeoisie*, neither party, it seems, wishing utterly to exclude the possibility of some future agreement.

After 1635 Catalonia was subjected to pressure from both France and Castile. The problem then became one of whether this discontented *bourgeoisie*, although opposed to Olivares' centralizing policy, would be able to prevent an alliance between the more extreme Pyrenean nobility and Cardinal Richelieu. In 1638 this latter alliance became more probable, as the balance of power swung toward the nobility with the election of a fervent Catalan patriot, the Canon of Urgel, Pau Clarís, as president of the *generalidad* (autonomous government of Catalonia). At the same time, in Castile the party led by Cardinal Borja and the *protonotario* of the Council of Aragon, Jerónimo de Villanueva, which demanded a more intransigent policy toward Catalonia, gained ground.

When Olivares, bent on extracting financial assistance from the Catalans, decided to launch an offensive against France from Catalonia, the billeting of soldiers there produced a revolt among the peasantry (May 1640). Most of the aristocracy and upper *bourgeoisie* remained faithful to the Spanish crown. The revolutionary solution, however, and the subsequent incorporation of the principality with France (January 1641) were imposed by the peasantry and by the lesser nobility, who reflected the social instability of the times. Catalonia then remained the site of a civil war and a battlefield between Spain and France until the Treaty of the Pyrenees in 1659. During the course of the war a new move between Madrid and the moderates in Barcelona led to the defeat of the extremists with the capture of Barcelona by Don John of Austria in October 1652, and the Catalan revolution ended with the reincorporation of the principality of Catalonia with the crown of Philip IV in January 1653. In October 1640, while the Spanish government was preoccupied with affairs in Catalonia, a successful revolt in Lisbon proclaimed Portugal's independence under the duke of Braganza, who became John IV, though it was not until the Treaty of Lisbon in 1668 that Spain finally recognized Portugal's independence (*see* PORTUGAL: *History*).

The economic and financial distress of the monarchy was aggravated further by the burden of these wars. Philip IV was forced to resort to inflation, especially in the years 1634–35, and so great was the increase in prices that some sort of deflationary measures became essential. From 1656 until the deflation of 1680 (in the reign of Charles II) the country endured a very real monetary crisis, which marked the lowest point of the depression of the 17th century. This fact explains why social distress was even greater than in the reign of Philip III.

Charles II.—Philip IV's son Charles II (*q.v.;* 1665–1700), the last of the Spanish Habsburg kings of Spain, came to the throne as a minor, and his reign began with the ten-year regency of the queen mother, Mariana of Austria. In domestic affairs, the ruin of Olivares' policy had produced a strong reaction in favour of the decentralization of government. This was accompanied by some economic improvement of the peripheral regions of Spain, notably in Catalonia after 1680, in contrast to the position in Castile. This improvement, however, was due partly to the fact that from about 1680 gold from Brazil did much to improve the economic and financial position throughout Western Europe. From 1665 to 1680 several rises in prices resulting from government action had proved disastrous and made essential the deflation of 1680 which resulted in a 45% drop in prices and restored some order to the monetary chaos in Spain. By 1686 the position was becoming more stable and a slow recovery in the economy was in progress. In 1680 the first minister, the duque de Medinaceli, created the Junta de Comercio y Moneda and inaugurated an economic policy based on the mercantilist principles of the French minister Jean Colbert (*q.v.*). Trade increased, especially through the port of Barcelona, and there was some development of Castilian industry. Charles II promulgated an order declaring that commercial activities were compatible with noble birth. The beginnings of the drastic reforms of the economy, and of the administrative system of Spain, that the Bourbons were to carry out in the 18th century, can in fact be seen in these minor reforms.

Wars with France.—In foreign affairs Charles was forced to involve Spain in continuous wars against the imperialism of Louis XIV of France. In 1667 Louis claimed the Spanish Netherlands on behalf of his wife Maria Teresa, the daughter of Philip IV's first marriage and consequently half sister to Charles II. The resulting War of Devolution (*q.v.;* 1667–68) produced a European coalition against France, but by the Peace of Aix-la-Chapelle (1668) Spain ceded to France several places in Flanders. A further war by Louis XIV from 1672 to 1678 (*see* DUTCH WARS), which was ended by the Peace of Nijmegen, deprived Spain of the Franche-Comté and resulted in frontier changes in the Low Countries. However in the War of the Grand Alliance (*q.v.;* 1689–97), despite Spanish defeats, Louis negotiated the generous Peace of Rijswijk, whereby he evacuated his forces from Catalonia and restored to Spain its possessions in Flanders as set down at the Peace of Nijmegen. By this time Louis had no wish to prejudice the Spaniards against him, for the question of the succession to the Spanish throne (to which France had strong claims, *see* below) was becoming acute.

The lack of any issue from Charles II's two marriages, to Marie Louise d'Orléans and Maria Anna of Neuburg, had led to great speculation among the major European powers as to his successor. Rival claims from both France and the emperor Leopold I, and fears by the European powers of dominance by France if the former were successful, resulted in the treaties of 1698 and 1699 for the partition of the Spanish Empire. Anxious to preserve the unity of his empire, Charles II in October 1700, a month before his death, made a will naming as his sole heir Philip, duc d'Anjou (later Philip V of Spain), a younger grandson of Louis XIV. Louis' acceptance of the will, despite his obligations to the partition agreements, and his declaration in December 1700 that Philip was not debarred from the succession to the French throne, led directly to the War of the Spanish Succession (1701–13; for details of the dynastic claims to the succession, of the partition treaties, and of the war itself, *see* SPANISH SUCCESSION, WAR OF THE). (J. RE.)

I. THE BOURBON DYNASTY

Philip V.—In the first half of the 18th century, Spain played an active part in foreign affairs, partly because of the reforms that followed the accession of a French prince, Philip V (*q.v.;* 1700–January 1724 and August 1724–1746). Louis XIV sent Jean Orry (*q.v.*) to inspect the Spanish finances in 1701, and in 1702

Orry was put in charge of military finances. After 1705 the work of reform was considerably helped by the arrival of Michel Amelot as French ambassador, and, even though Amelot was recalled in 1709 and Orry was out of Spain between 1706 and 1713, the reforms which they had initiated did much to revive Spain. The basic object of Orry's reforms was to centralize the financial administration, a task made easier by the fact that the old kingdoms of Aragon and Valencia and the principality of Catalonia, which had declared for the archduke Charles (from 1711 the emperor Charles VI), the Austrian Habsburg claimant to the Spanish throne, were eventually conquered, so that their financial independence could be ended. Orry also worked to simplify the methods of collecting taxes, though it was not until after 1713 that his plan of one tax collector in each province with only one assistant in each area came into operation. When Orry proposed to tax the church, however, he was dismissed (1715). The treasury had been freed of considerable sums which had previously been granted every year as pensions; income from alienated crown property was resumed for one year, and treasure brought by private individuals from the Indies was taxed heavily. Spain was fortunate in that Philip V had no extravagant favourites, such as Philip III and IV had had in Lerma or Olivares, and his shabby court was not so costly as the luxurious court of Philip IV. From 1702 to 1714 prices had risen a little because of bad harvests, plague, and an exceptionally cold winter, but this rise was very slight by comparison with what had happened in the 17th century; from 1714 to 1732 prices were generally stable.

Administrative and political centralization was increased as the districts which had supported the archduke Charles were reconquered. In 1707 the *fueros* of Aragon and Valencia were ended, and municipal government on Castilian lines was introduced in those provinces. The eastern kingdoms ceased to be regarded as separate. The office of viceroy was abolished and in its place the king appointed captains general, one of whose functions was to preside over the *audiencias* (high courts of justice) set up at Saragossa, Valencia, Barcelona, and at Palma de Mallorca in the Balearics. The extinction of the *Cortes* of Aragon and Valencia in 1709 and of Catalonia in 1724 was another sign of the increasing centralization. In achieving these reforms Philip V took little part. His main preoccupation in these years was the war for the succession, and his determination to retain the throne of Spain was loyally supported by his young wife María Luisa of Savoy. On the whole Philip's foreign policy followed the line laid down by Louis XIV. The loyalty of the Spanish court to France was encouraged by the influence of Marie Anne de la Trémoïlle, princesse des Ursins (*q.v.*), who had been sent to Spain by Louis XIV in 1701 to become chief lady of the bedchamber to the queen of Spain.

By the treaties of Utrecht (1713) and of Rastatt (1714), which ended the war, Philip was recognized as king of Spain and of Spanish America, but lost the Spanish possessions in Italy (Milan, the kingdom of Naples, and the Spanish bases on the Tuscan coast), Sardinia, and the Spanish Netherlands to the emperor; Sicily to the king of Savoy; and Gibraltar and Minorca to England. Philip had previously renounced his claim to the French throne. Philip and the emperor, however, refused to make peace with each other and remained technically at war.

Isabella Farnese.—In 1714 María Luisa died and the choice of a second wife for Philip fell on Isabella Farnese (*q.v.*), niece and stepdaughter of the duke of Parma, who was commended to Madame des Ursins as being young, countrified, and completely inexperienced politically. During her journey overland to Spain, Isabella met Maria Anna, the widow of Charles II of Spain, and also had opportunities for considerable conversations with Giulio Alberoni (*q.v.*), the envoy at Madrid of the duke of Parma. Although inexperienced, she quickly realized that she must break the power of the princesse des Ursins. In her first interview with the favourite, Isabella showed her character by exiling her (Dec. 23, 1714). For a few years Alberoni was the dominating influence, though the official chief minister was Cardinal Francesco del Giudice. Alberoni was convinced that Spain had the resources to become a great power. He was also deeply concerned for the small states of Italy, particularly Parma, and wanted to free them from the emperor's influence. This he hoped to do with the help of Spain, if Spanish policy could be directed by the new Farnese queen.

Foreign Policy.—The death of Louis XIV in September 1715 provided Alberoni with an opportunity to carry out his plans. Philip V had already shown signs of wishing to escape from French control. In December 1715 Alberoni persuaded the Spanish court to conclude a commercial treaty with Britain which eradicated the difficulties to British trade that had arisen from the shortcomings of the commercial treaty signed at Utrecht in 1713. This was followed in May 1716 by another agreement with Britain which gave satisfaction for grievances arising out of the Asiento Treaty (*see* ASIENTO) of 1713, permitting Britain to supply Negro slaves to Spanish America. In July 1716 Cardinal Giudice fell from power and Alberoni's influence, though still unofficial, increased, but he was badly discredited when England and the emperor concluded the Treaty of Westminster, 1716, and when this was followed in November 1716 by an alliance between England and France. The Spanish court, fearing that the emperor might try and increase his power in Italy, used the pretext of the arrest in Lombardy of the Spanish Inquisition General, Cardinal Molinés, by imperial authorities, to launch a successful attack in November 1717 on Sardinia, a former Spanish possession. This was followed by an attack on Sicily in July 1718.

For a time it looked as if Spain might again embroil all the powers in war. In August 1718 Great Britain, France, the emperor, and the United Provinces formed the Quadruple Alliance to settle the differences in Southern Europe and if necessary to coerce Spain to accept their terms. Later that month the English destroyed the Spanish fleet off Cape Passaro, Sicily; in 1719 French troops overran the Basque provinces; and finally in 1720 Philip V accepted the terms of the Quadruple Alliance as a basis on which peace could be reestablished between Spain and the empire. The emperor renounced his claim to the Spanish crown, and Philip V renounced his claim to the Spanish territories in Italy, lost to the emperor in 1713. Philip agreed to restore Sardinia to the emperor (who in fact gave it to Savoy) and to relinquish his claims to Sicily, which passed to the emperor. Some issues still undecided were to be settled at a congress to meet at Cambrai, in France. Alberoni had been dismissed in December 1719, but he and Isabella had achieved something. In the Quadruple Alliance the powers acknowledged the claim of Don Carlos (afterward Charles III of Spain), Philip's eldest son by Isabella, to succeed to Parma and Tuscany, territories to which Isabella had dynastic claims.

With Alberoni's dismissal Spain relapsed temporarily into a state of stagnation. Alberoni had carried the administrative reforms of Orry a stage further and simplified the institutions of government. He had abolished the *Despacho*, or small Cabinet Council, and had reduced the powers of the larger *Consejo de Estado*. The old councils of Castile, Finance, War, and the Indies remained, but their influence had declined. Spanish affairs were, in fact, in the hands of three secretaries of state, but in 1720 there was no statesman capable of exploiting the power of one of these posts. The marqués de Grimaldo became the chief of the secretaries of state, but he was not a statesman. Under his guidance Spain in 1721 renewed its alliance with France and resumed cordial relations with England. Isabella hoped that England and France would help to secure for Don Carlos effective possession of the Italian lands, but the dispute between Spain and the emperor was not easily settled and negotiations at the Congress of Cambrai dragged on from 1721 to 1724.

Abdication of Philip.—In January 1724 Philip V caused a sensation by abdicating in favour of Luis, his eldest son by his first wife. Whether he did this to strengthen the claim he intermittently made to the throne of France or because he was tormented by religious scruples, knew himself unfit to govern, and was only putting into effect an earlier vow to abdicate is uncertain. The episode ended swiftly for in August 1724 Luis died of smallpox and Philip yielded to the pressure of Isabella, France, the papacy, and the Council of Castile to resume the crown. The abdication

had had very little effect on Spanish policy, but when it became clear that France would not take active steps to secure the Italian possessions for Don Carlos and when in 1725 the French court returned to Spain the infanta Mariana (b. 1718), who had been sent to France on her betrothal to Louis XV at the time of the alliance in 1721, Isabella and Philip decided to abandon the French alliance and try a direct approach to the emperor. The negotiations with the imperial court at Vienna were entrusted to a remarkable Dutchman Jan Willem Ripperdá, who managed to achieve peace and even an alliance with the emperor in 1725 by the Treaty of Vienna. Ripperdá reported in Spain that the emperor had requested that he should be made chief minister, but he was soon exposed as having misled both the emperor and the rulers of Spain by rash promises and was dismissed in May 1726.

Succession to Parma.—The improved relations with the emperor, however, soon cooled and Spain reverted to a policy of friendship with England and France, signing the Treaty of Seville with them in 1729. On the death in January 1731 of Antonio, the last Farnese duke of Parma, the emperor seized the duchy. The dispute over Parma was finally solved by the diplomacy of England, which in return for accepting the Pragmatic Sanction, guaranteeing the Austrian succession to Charles VI's daughter Maria Theresa, persuaded the emperor in the Treaty of Vienna (1731) to cede Parma to Don Carlos and invest him with the reversion to Tuscany. In 1733 Spain concluded the first Family Compact with France, joining that country in the War of the Polish Succession (*q.v.*). As a result, by the Peace of 1735 (ratified in 1738) Don Carlos was confirmed in his conquest of Naples and Sicily in return for relinquishing Parma and his claim to Tuscany.

War with England.—In 1739 war broke out between Spain and England. Since 1713 there had been considerable causes of friction between them, particularly the large amount of illicit trade carried on by the English with the Spanish colonies on the American mainland and in the West Indies. The Spanish colonial governors, finding it difficult to fit out ships to patrol the coasts, allowed adventurers and privateers to intercept smugglers, and British merchants claimed that their ships were illegally stopped and searched. Although neither the English prime minister Sir Robert Walpole nor the Spanish secretary of state the marqués de Patiño (*q.v.*) wanted war, mercantile clamour in England could not be pacified, and in 1739 the war known as the War of Jenkins' Ear broke out (*see* JENKINS, ROBERT). In 1740 this war merged with the War of the Austrian Succession (*q.v.;* 1740–48), and in 1743 Spain concluded with France the second Family Compact, whereby France undertook to secure Milan, Parma, and Piacenza for Don Philip, Isabella's second son, and to help Spain recover Gibraltar and Minorca. During the war, Spanish forces fought in Italy, achieving some notable success. In 1746 Philip V died. During his reign the energy and efficiency of Orry, of Alberoni, and of the marqués de Patiño had done something to restore Spain's prosperity and in particular to improve the royal revenue and develop efficient dockyards.

Ferdinand VI.—Ferdinand VI (*q.v.;* 1746–59), Philip V's fourth son by his first wife, was a pacific, unambitious man. The treaty of Aix-la-Chapelle (1748) ended the War of the Austrian Succession and assigned Parma, Piacenza, and Guastalla to Don Philip. In 1750 Spain concluded an agreement with England ending the *asiento* in return for £100,000. Don José Carvajal y Lancáster, who directed Spanish policy until 1754, was determined to restore the greatness of Spain and decided that the best policy was to tolerate one expensive but powerful friend, England. Under his guidance Anglo-Spanish relations entered upon an era which has been called "the Seven Years' Peace." The other great minister of the reign Cenón de Somodevilla, marqués de la Ensenada (*q.v.*), though he inclined to a pro-French policy and had been responsible for the second Family Compact of 1743, accepted the pacific policy of Ferdinand VI and occupied himself with reviving agriculture, stimulating mining and trade, and developing the navy. By the middle of the century the population of Spain had increased from about 5,700,000 in 1700 to 7,500,000, though estimates of the exact figures vary considerably. In 1746 the first of the economic societies was founded to revive an interest in agriculture. Academies of history and of arts had been set up in the last years of Philip's reign, and a royal college was begun to educate sons of the nobility. The Inquisition, which under Philip V had held 728 autos-da-fé and imposed 14,000 sentences, gradually declined in importance under Ferdinand VI. Unfortunately after the death of Carvajal in 1754 it was impossible for the new minister Richard Wall to prevent increasing friction with England, which arose mainly out of colonial conflict in the Indies. (J. O. Li.)

Charles III.—The reign of Charles III (*q.v.;* 1759–88), eldest son of Philip V and Isabella, and half brother of Ferdinand VI, can be characterized as one of enlightened despotism, for in that period reforms were carried out by a monarch who was much more absolute than his predecessors, using ministers who were influenced by reforming ideas, then current throughout Europe. He had two problems: first, the economic condition of Spain, an amalgam of chronic unemployment, huge untilled estates, a chaotic currency, and the absence of industry; and second, the political and administrative problem, the lack of effective agencies both for the formulation of policy and for its application. Charles III and his ministers set themselves to redress this situation, but their achievements should not be exaggerated. Moreover, Charles III's absolutism was less effective in practice than in theory: as late as 1787 there were in Spain over 10,000 towns and villages subject to seignorial jurisdiction and thereby removed from direct royal control. Nevertheless Charles III did give Spain a more modern political appearance and some measure of economic recovery. His experience as king of Naples (1735–59), his conviction of his reforming mission, and his devotion to work and duty adequately compensated for his rather limited intelligence. Above all he was successful in his choice of advisers and ministers, selecting them neither from the traditionalists nor from the aristocracy but from a small and enlightened group of men who supplied the ideas and set the pace of reform.

Yet Charles III's early ministerial appointments were not popular in Spain and his preference for foreigners was resented. The most prominent of his ministers were the Italians, the marqués de Squillace, secretary of state for war and finance, and the marqués de Grimaldi, secretary of state for foreign affairs. Spain's disastrous participation in the Seven Years' War (*q.v.;* 1756–63), the rise in the price of food caused by general inflation and a series of bad harvests between 1763 and 1765, and the higher taxes demanded by Squillace to pay for public works increased the unpopularity of the foreign advisers. Finally, Squillace's attempt to enforce an old law forbidding men to wear in Madrid their broad-brimmed slouch hats and long capes, on the ground that they hindered the detection of criminals, provoked violent riots in the capital in March 1766 which spread to other towns in central Spain. The king was forced to accept the terms of the insurgents: the exile of Squillace, the revocation of the dress order, and the lowering of food prices. The conde de Aranda (*q.v.*) was called in to restore order (holding office to 1773), and was given the presidency of the Council of Castile. Within a year he was able to revoke most of Charles's concessions.

Suppression of the Jesuits.—The riots of 1766 were now used as an excuse to attack the Jesuits who were regarded as a threat to the supreme authority of the crown and to its interests in Spanish America. It was rumoured that the riots had been planned by groups of nobles and clergy who wished to evict Squillace and discourage Charles from further reforms. The truth of these reports is still an open question, but they were useful to the government and a royal commission found the Jesuits guilty of using their influence to incite riots. On this evidence Charles III ordered the expulsion of the Jesuits, and the decree was enforced in Spain and the colonies in April 1767. The subordination of the church to the state in Spain was completed by the promotion of churchmen of regalist and antipapal views, by the decree forbidding the publication of papal bulls in Spain without royal permission, and by the curtailment of the jurisdiction of the Inquisition. In 1776 Charles III removed his last prominent foreign adviser when the conde de Floridablanca (*q.v.*) replaced Grimaldi.

Administrative and Economic Reforms.—Charles III continued and perfected the administrative reforms introduced by Philip V, whereby individual ministries gradually replaced the Habsburgs' conciliar system of government, and the concentration of power in the hands of a small number of men continually in contact with the king gave policy a new vigour. These ministers promoted policy, extended the central power throughout Spain, stimulated the intendants, and inaugurated administrative reforms in the collection of revenue, in national defense, and in local government. Finally, the various ministries were coordinated by Floridablanca into a *Junta de Estado*, a type of cabinet, which met frequently to discuss policy collectively and which in 1787 was given a definite constitution. Charles III's most urgent problem was, however, the economic condition of the country. The rise in population (from about 6,000,000 to more than 10,000,000 in the course of the 18th century), combined with inflation, led after 1750 to a rush for land in which the already powerful landowners increased their holdings, while the condition of tenants and landless labourers in Castile became even more desperate. In spite of the limitation of the pasture privileges of the Mesta (sheepfarmers' guild) in the interests of farmers of arable land and the creation of agricultural colonies in the Sierra Morena, nothing effective was done to remedy the greatest defect in the Spanish land system: huge and largely untilled estates held by the church and nobility. The planners' main concern, however, was not agriculture but colonial commerce and domestic manufacture. Support was given to the quasi-official economic societies, formed to promote the prosperity of the country by applied science. To improve communications the state itself invested money in public works, such as road and canal building. Official encouragement was given to industry. In 1770 a royal decree announced that there was no incompatibility between aristocratic or gentle status and engaging in a craft. A number of state-supported factories employing foreign craftsmen were set up to produce luxury goods, hitherto imported. Domestic manufacture was protected: by 1771 the import of all foreign cotton cloths was prohibited, a policy particularly favourable to Catalan industry.

Charles III's most effective economic measure, however, was the opening of colonial commerce to freer trade. In 1765 Spain ended the policy of restricted ports of clearance from Spain and of entry to the Indies. Trade with the colonies was now open to all the main Spanish ports, and trade with Spain was open to many more Caribbean ports. Gradually the free-trade area was extended, and by 1789 Spain had abandoned the commercial regulations held sacred for more than 200 years. These reforms injected new life into the domestic and imperial economy. The industries of Catalonia and Biscay (Vizcaya), especially cotton and metallurgy, whose growth had been one of the influences determining the measures of freer trade, further benefited from the resulting expansion. Shipping between Spain and the colonies multiplied rapidly, and the whole trade with Spanish America is said to have expanded by as much as 700% in the period from 1778 to 1788.

Colonial Wars.—Commercial objectives were closely connected with imperial defense. Spain's most powerful rival was Great Britain, and Charles III's anxiety to maintain a colonial balance of power was one of the main objectives of his foreign policy. For this reason he made with France (August 1761) the third Family Compact, which created an offensive and defensive alliance between the two Bourbon powers and took Spain into the Seven Years' War when England, already at war with France, declared war on Spain in January 1762. The war proved a disaster for Spain as well as for France. England captured Havana and Manila, and although both were restored at the Peace of Paris in 1763, Spain was forced to cede to Britain Florida and all Spanish territory in North America east of the Mississippi River. From France, Spain gained Louisiana—and a new frontier to be defended against Britain. Despite this humiliation, however, Charles hesitated to intervene against Great Britain in the American War of Independence (1775–81), for Spain could not profit from the precedent of colonial independence. When Spain finally followed France into the war in 1779, it pursued its own interests without giving much direct support to the British colonies and without recognizing their independence. Spanish forces reconquered Florida, occupied the British outposts in the Bahamas, and expelled the enemy from their logging bases in Honduras. A prolonged siege of Gibraltar (1779–83) was unsuccessful, but an expedition to Minorca recovered the island for Spain in February 1782. By the Peace of Versailles (Sept. 3, 1783) Spain regained Florida and retained Minorca but restored the Bahamas to England and gave the English certain trading rights in Honduras. Despite its defeats Spain came out of the war with moderate success.

Charles IV.—The reign of Charles IV (*q.v.;* 1788–1808), the second son of Charles III, was marked by the rule of the favourite, Manuel de Godoy (*q.v.*), and the impact of the French Revolution. The king himself, intellectually feeble and lacking the willpower of his father, was powerless to direct events. At first he tried to continue the reforming policy of Charles III and he retained Floridablanca as his secretary of state. The moribund *Cortes* of Castile, convoked in 1789 to recognize Charles IV's son Ferdinand (later Ferdinand VII) as heir to the throne, received with apathy a royal proposal to limit the privilege of entail of the nobility. But events in France ruined the chance of any reforming program. The flood of revolutionary propaganda crossing the border, while it found little response in Spain, startled Floridablanca into a series of panic-stricken repressive measures at home and a policy of hostility toward the revolutionary cause in France, a policy which was regarded in Spain as endangering the life of Charles's cousin, Louis XVI. Floridablanca was therefore dismissed in February 1792, but his successor, the conde de Aranda, fared little better and was replaced in November 1792 by Godoy, a former guards officer who, under the protection of the queen María Luisa, had risen rapidly in military rank and government position and whose appointment scandalized the Spanish public.

Relations with France.—Godoy's attempt in 1793 to save the life of Louis XVI by bribing the vote in the Convention failed. Pressed by England and bound by the Family Compact, Charles IV declared war on the French republicans in 1793. A French army invaded Spain (*see* FRENCH REVOLUTIONARY WARS) and was only bought off by the Treaty of Basel in July 1795, whereby Spain ceded to France its portion of the island of Hispaniola, known as Santo Domingo. Spain, weak in material resources and faced with a hostile Britain, was now tied ever more closely to French interests. In 1796, by the Treaty of San Ildefonso, Charles joined France in the war against England, during the course of which the Spanish suffered a naval defeat off Cape St. Vincent (February 1797; *see* ST. VINCENT, BATTLE OF) and lost Trinidad and Minorca. The French, suspecting Godoy's loyalty to the alliance, procured his dismissal in 1798. The advent of Napoleon Bonaparte to power from 1799 meant further subordination of Spain to France. In a second Treaty of San Ildefonso (1800) France promised, in exchange for Louisiana, to aid Spain to enlarge the duchy of Parma. Pursuing his hostility against England, Napoleon forced Spain to attack Portugal in 1801, and Godoy himself, now back in power, led an invading army which forced Portugal, in return for a Spanish guarantee of Portugal's territorial integrity, to undertake to close its ports to England. In 1802 a general peace was secured by the Treaty of Amiens: Spain recovered Minorca but not Trinidad.

In spite of disastrous conditions at home, heavy taxation, and an empty treasury, Spain was forced to pay heavy indemnities to France and was dragged into yet another war with England (December 1804; *see* NAPOLEONIC WARS). In October 1805 a Franco-Spanish fleet was destroyed off Cape Trafalgar (*see* TRAFALGAR, BATTLE OF), a crushing blow to Spanish morale and to Spain's ability to protect its overseas possessions. This was not all. Charles IV and Godoy, subservient to Napoleon in spite of themselves and subject at home to the growing opposition of the Fernandista Party (the supporters of Charles IV's heir Ferdinand), subscribed to the Treaty of Fontainebleau (October 1807) by which Napoleon and the Spanish government agreed upon the conquest and partition of Portugal. The French army which conquered Portugal (1807) also occupied parts of northern Spain, and Napoleon, whose intentions were now becoming clear, claimed all

of Portugal and certain provinces of northern Spain. Unable to organize government resistance, Godoy persuaded Charles IV to imitate the Portuguese royal family and escape to South America. The journey from Madrid was halted at Aranjuez, where a revolt organized by the Fernandista faction (March 17, 1808) procured the dismissal of Godoy and the abdication of Charles IV in favour of Ferdinand. Napoleon, taking advantage of the situation, ordered Gen. Joachim Murat to occupy Madrid and by a mixture of threats and promises induced both Charles and Ferdinand to proceed to Bayonne for conferences. There, on May 5, 1808, Napoleon forced Ferdinand to abdicate in favour of Charles, and Charles in favour of himself. In exchange Napoleon promised that Spain should remain Catholic and independent, under a ruler whom he would name. He chose his brother Joseph Bonaparte. However on May 2 the people of Madrid had already risen against the invader and the war for Spanish independence (1808–14) had begun. For details of the war *see* the article PENINSULAR WAR. (Jo. L.)

The War of Independence.—The rising in Madrid began the movement which ultimately proved fatal to Napoleon's power. Although the Madrid revolt was ruthlessly suppressed by the French, provincial insurrections took place throughout Spain, and the Spaniards showed great capacity for guerrilla warfare. The French were repulsed from Valencia and Gen. Pierre Dupont, who had advanced into Andalusia, was compelled to retreat and ultimately to capitulate with all his army at Bailén (July 23). The Spaniards now advanced upon the capital and expelled Joseph Bonaparte (August).

To some extent this was a civil war, for a small but not unimportant section of Spaniards, who had been much influenced by the doctrines of the French Revolution, continued to see in France the bulwark of liberal principles and looked to Joseph and the constitution he had drawn up at Bayonne as marking the dawn of responsible government in Spain. The struggle for independence, though in itself inevitably productive of new currents of thought in a progressive minority, was to seem in retrospect to have been a struggle no less against the spirit of the age. But the combined defection of the crown, of its senior statesmen, of a large part of the higher nobility, and of the intellectual *Afrancesados* made the reaction of the Spanish people, thus left leaderless, the more remarkable. The provincial committees which had been set up now created a single central junta which sat at Aranjuez. The military superiority of the French ruled out hopes of an immediate victory, but Napoleon himself was compelled to come to Spain to direct operations. The French campaign, leading to the capture of Madrid (December 1808), forced the junta to retreat southward to Seville. In January 1810 Gen. Nicolas de Dieu Soult began the conquest of Andalusia and with the fall of Seville in the same month the central junta fled to Cádiz. Only the obstinate resistance of the duke of Wellington in Portugal, the continuous activity of the *guerrilleros,* and dissensions among the French saved the peninsula from final submission.

The Spanish *Cortes* had become in the course of the 18th century little more than a rubber stamp. Under Philip V the *Cortes* of the other regions had been merged in the *Cortes* of Castile. Now, under the influence of the ideas of revolutionary France, the reformist patriots of Cádiz planned their reestablishment on a more democratic though still national basis, and in September 1810 a new *Cortes* was convened in that city. It included for the first time delegates of the colonies, chosen like those of Spain itself, from among those citizens who were present in Cádiz. The third estate (bourgeois), with 184 deputies, was sufficient to swamp the nobles and the clergy, and the debate on the new constitution soon produced a deep cleavage between *Liberales*—it was then that the term took on its party political connotation—and *Serviles* (supporters of absolute monarchy). The former won the day, and the constitution of 1812 was duly promulgated. Its 384 articles gave to the Spanish nation the exclusive right to determine its fundamental laws. The king would legislate with the *Cortes,* now a single chamber; but royal decrees, to be valid, required the countersignature of a minister, and ministers were responsible to the *Cortes.* Freedom of the press, though not of religious belief, was assured, and legal codes were made uniform for the whole country. The constitution was unworkable in many respects and never achieved more than a symbolic importance; but by vesting in the people for the first time the responsibility for determining under what laws they should live, it closed an epoch in their history and established constitutionalism as the primary characteristic of the new age. Its influence was also profound in two other directions. Its radical idealism, offending the mass of the people, was partly responsible for the support Ferdinand received at his restoration in 1814 (*see* below) and prepared the way for one of the most reactionary regimes in Spanish history; the tendency persisted thereafter for Spanish politics to swing from extreme to extreme. It also gave later warrant for the identification of liberalism with both anticlericalism and centralization.

From his base in Portugal, which he had successfully defended, Wellington in 1812 began his gradual advance into Spain. His defeat of Marshal Jean Baptiste Jourdan at Vitoria on June 21, 1813, finally decided the issue in the peninsula. Joseph Bonaparte withdrew from Spain, and Wellington fought his way across the Pyrenees into France. Napoleon, after his crushing defeat at Leipzig (October), recognized the impossibility of retaining his hold on Spain by releasing Ferdinand, who had been detained by the French at Valençay since his abdication in 1808.

Ferdinand VII.—Before entering Spain in March 1814 Ferdinand VII (*q.v.;* 1808 and 1814–33) had undertaken to maintain the constitution of 1812, and on reaching Figueras he was met by a formal demand in this sense from the *Cortes.* But he was quick to appraise the true temper of the nation, and in rejecting the demand now he was supported alike by the army, the church, and the people. Had he been capable of governing well, he might have ruled despotically for a considerable time. He was, however, cruel, cowardly, and without real ability. Dominated by a *camarilla* of favourites, he changed his ministers incessantly and was consistent only in his ferocious persecution of the *Liberales.*

Several minor revolts between 1814 and 1817 were easily crushed, but that of January 1820, beginning as a mutiny at Cádiz in protest against the sending of an expeditionary force to crush rebellion in the South American colonies, became a revolution. Its leader and hero, Gen. Rafael del Riego, was one of a number of officers, many of them former prisoners in France, who now subscribed to liberal doctrines. Six years of tyrannical excesses had turned the army largely against the king and from 1820 to 1823 Ferdinand was a prisoner in the hands of a section of his subjects, who proclaimed once more the constitution of 1812. Ferdinand appealed for help to the Holy Alliance (*q.v.*). As early as 1820 the emperor Alexander I of Russia had vainly proposed joint intervention. In 1822 the question arose again at the Congress of Verona, France proposing to march into Spain to restore Ferdinand.

Great Britain saw in the demand only a pretext for reviving traditional Bourbon ambitions in the peninsula and protested vigorously; but the mandate was granted by a majority of the powers and on April 7, 1823, Louis Antoine de Bourbon, duc d'Angoulême, crossed the Bidassoa (Bidasoa) River at the head of a powerful army. The result was a startling proof of the flimsy hold of liberalism on the Spanish people. What Napoleon had failed to accomplish in years, Angoulême seemed to have achieved in a few weeks. Napoleon, however, had sought to impose upon Spain an alien dynasty; Angoulême came to restore the Spanish king "to his own" and found some Spaniards forthcoming with active support and the majority at least tacitly cooperative. The *Cortes,* taking the king as prisoner, fled again to Cádiz, where after a brief siege it surrendered (September). Ferdinand, alleging compulsion, refused to honour the amnesty he had sworn, and the French troops witnessed with helpless indignation an orgy of cruel reaction begun under the protection of their bayonets.

The Spanish Colonies.—The emancipation of Spain's American colonies was an indirect result of Napoleon's detention of Ferdinand and invasion of Spain in 1808. Juntas in the various administrative capitals overseas assumed power, first in the name of Ferdinand against Joseph Bonaparte, then in the name of the

colonies themselves against Spain. Some of these had already become independent *de facto* by 1810, and many more became so in the ten years following; and the recognition of their independence *de jure* was, for Great Britain at least, merely a question of time. When the French invasion of Spain was seen to be inevitable in 1823, George Canning, the British foreign secretary, informed the French government that Great Britain would not tolerate any subjugation of the Spanish colonies by foreign force. The United States, though declining to act in concert, followed with the famous message of Pres. James Monroe (Dec. 2, 1823; *see* MONROE DOCTRINE) intimating his country's opposition to any interference by Europe in the Americas. The Republic of Colombia had already been recognized by the United States in 1822. Great Britain recognized Mexico and Colombia in 1824 and only delayed recognition of the other new states until they should have given proof of stability. There now remained to Spain, of its far-flung empire, only the islands of Cuba, Puerto Rico, and the Philippines.

The Succession Question.—Ferdinand, still childless on the death of his third wife María Josefa Amalia in 1829, married María Cristina I (*q.v.*) of the Two Sicilies in that year and in so doing threatened the mounting hopes of his brother Don Carlos (*q.v.*) regarding the succession. Don Carlos was also an extreme reactionary, and the clash of ambitions threw María Cristina on the support of the Liberals. The birth of a daughter Isabella in 1830 greatly complicated the issue. By the ancient law of Castile and León women could rule in their own right. This right had, however, been abrogated by an act of 1713 designed to prevent any union of the crowns of Spain and France; and, although Charles IV had restored the former position in 1789, his enactment had never been published and its validity was now hotly disputed. Hence the birth of Carlism (*q.v.*), the name of the movement by which the supporters of Don Carlos and his heirs were known, which was for more than half a century to be a disrupting factor in the history of Spain. When, on Sept. 29, 1833, Ferdinand died, his daughter was proclaimed queen as Isabella II (*q.v.;* 1833–68), with María Cristina as regent. The First Carlist War (1833–39) broke out almost immediately.

The Regency for Isabella II (1833–43).—María Cristina would have ruled despotically if she could, but the support of the army and control of the machinery of government were not in themselves sufficient to resist the Carlists, in whose ranks were to be found not merely the clergy and other ultraconservative elements but also large numbers of Basques, Catalans, and other peoples of the periphery who had been persuaded that their regional *fueros* were in danger and who supplied the real fighting strength of the movement in defense of them. The necessities of her position thus drove the regent to accept parliamentary institutions under a new constitution in 1837 which, though much strengthening the royal prerogative, was liberal and bore traces of the English Reform Bill of 1832. The constitution established a *Cortes* of two chambers, the upper house being elective, but gave the crown an absolute veto. The return from England and France of many exiles of the preceding decade also brought support to the liberal cause. But neither María Cristina nor her daughter ever genuinely accepted the principle of representative government and there ensued, within the Carlist War, a bitter struggle between Parliament and the parliamentary cause on the one hand and the crown on the other.

The First Carlist War, which was for the crown a dynastic issue and for the nation a conflict between irreconcilable political principles, involved Great Britain in military commitments on the government's side and threatened more than once to involve Europe in war. It ended with the Convention of Vergara (Aug. 31, 1839), a recognition of Carlist defeat. Baldomero Espartero (*q.v.*), the Liberal general, undertook to recommend to the *Cortes* the substantial confirmation of the Basque *fueros*, and Don Carlos left Spain for France. But the Carlist cause remained alive; and the *Cortes,* which insisted, in the name of national unity and uniformity, on whittling down the *fueros* until little more than administrative autonomy remained, ensured continuing Basque support for Carlism. An earlier measure for unity had been the supersession for administrative purposes, in 1833, of the various kingdoms of Spain by 49 provinces on the French model. From that year dates the Catalan *renaixença*, a resurgence of regional feeling at once cultural and political that was to have far-reaching consequences. Another enactment destined to provoke repercussions for many years was the acceptance in the constitution of 1837 of state responsibility for the upkeep of the church and the consequent disposal by the state of ecclesiastical property. The Jesuits, readmitted by Ferdinand VII, had been reexpelled in 1835.

With the removal of the Carlist threat to the throne in 1839, María Cristina was emboldened in her absolutist leanings, and now sought to have the constitution of 1837 overthrown. Failing in this, she directed an attack on the independence of the municipalities in 1840, which provoked a major crisis that culminated in her abdication (October). Espartero was proclaimed as regent in her place, and Spain had its first experience of the army in political control. After three disturbed years a military rising led by Gens. Juan Prim and Ramón Narváez (*qq.v.*), with liberal and moderate backing, drove Espartero likewise into exile (July 1843), and Isabella, then only 13 years old, was declared of age.

Isabella II.—The new reign proved but a continuation of the regency, a confused conflict between the attempts of the crown to rule despotically with a mere pretense of a *Cortes* and the nation's growing demand for honest and efficient parliamentary government. New constitutions (1845, 1852, 1855) alternated between the progressive and the reactionary and caused a spurious importance to be attached to the letter as distinct from the spirit of constitutionalism. Party leaders were almost always generals: Espartero, Narváez (leader of the "Moderates" or extreme conservatives), Leopoldo O'Donnell (*q.v.*), Juan Prim. As such they were unable, even where willing, to further the cause of civic responsibility in the nation at large.

The queen's marriage on Oct. 10, 1846, provoked international repercussions. Louis Philippe of France, seeking to revive the family alliance, constrained Isabella, with the aid of María Cristina, to wed her cousin Francisco de Asís de Borbón, who was believed to be impotent; on the same day Isabella's younger sister María Luisa Fernanda was married to Louis Philippe's son Antoine, duc de Montpensier. The affair broke the entente between England and France—Lord Palmerston having only agreed on condition that the second marriage waited on the birth of an heir to the first—and was a contributory cause of the downfall of Louis Philippe (*see* FRANCE: *History*).

The church's right to hold and acquire property, restored by a concordat of 1851, was again threatened in 1856 when Isabella was compelled to give assent to a bill disposing of church property. Finally, in 1858, an agreement was reached with the pope over the state's compensation for the appropriation of church lands. The major external event of the reign was the Moroccan War of 1859–60, but Spanish successes there led to the acquisition of only a small part of Morocco.

Cumulative discontents against the crown, reflected in the emergence of a republican party in 1854, culminated in a mutiny in September 1868 at Cádiz of a squadron under Adm. Juan Bautista Topete y Carballo, which became the signal for a general revolution. The stand for the queen made at Alcolea by Gen. Manuel Pavía y Lacy (*q.v.*), marqués de Novaliches, was an exception. Even her prime minister, Luis González Bravo, deserted her. Isabella crossed into France an exile, and her reign ended. The revolution of 1868 was the first to be openly directed against the dynasty. The "spurious race of Bourbon," it was boasted, had disappeared; and, as in 1810, sovereignty was again for the moment vested in the people.

J. AMADEO AND THE FIRST REPUBLIC, 1870–75

Most of the nation was, however, not yet ready for a republic, and a constituent *Cortes*, assembled in 1869, voted for a continuance of the monarchy under a different monarch; Gen. Francisco Serrano (*q.v.*), a leader of the revolution, was declared regent until one could be found. In the constitution of 1869 may be found, for the first time since that of 1812, the entire program of the

liberalism of the period. Monarchist opinion on the succession was divided, some favouring Isabella's son Alfonso (later Alfonso XII) under a regency, some the widower Ferdinand of Saxe-Coburg (formerly king-consort and then regent of Portugal), while others preferred the duc de Montpensier, or a Carlist, or even the aged Espartero. The search for a democratic king, said Prim, the prime minister, was like looking for an atheist in heaven. The offer of the crown to Prince Leopold of Hohenzollern-Sigmaringen proved the spark that fired the Franco-German War (*q.v.*).

At length, in August 1870, Amadeo (*q.v.*; 1870–73) of Savoy, second son of Victor Emmanuel II, accepted the offer of nomination. He was proclaimed king on Nov. 16, and landed in Cartagena on Dec. 30. On that day Prim died as a result of an attack made on him by an assassin. Amadeo's reign was a period of turmoil and confusion. The monarch, the tool of intriguing politicians, was looked on as an intruder by men of principle, royalist and republican alike. The Second Carlist War (1872–76) began in the north. There was republican agitation in the towns and when the first honourable excuse presented itself Amadeo resigned (February 1873).

The First Republic.—Disillusionment with monarchy was for the moment complete, and the *Cortes* proclaimed Spain a republic. New elections were held (May) to a constituent *Cortes*, but the republic ran its brief and tempestuous course without a constitution. Beyond initial acceptance of the federal idea there was little agreement on first principles. Four presidents held office within the year: Estanislao Figueras, Francisco Pí y Margall, Nicolás Salmerón, and Emilio Castelar y Ripoll (*q.v.*). Ministries never knew stability, and many regions disavowed the authority of Madrid and proceeded to act independently. In the south, several towns went beyond federalism and pronounced themselves "cantons." The cantonalists in Murcia seized Cartagena and the Spanish navy in its harbour; the fleet was recovered for the government only by the help of British and German squadrons. The republic had further to contend with the Second Carlist War, with monarchist opposition, and with an insurrection in Cuba (the Ten Years' War; 1868–78).

As it grew ever clearer that only the army could restore authority and order, one major plank in the republican program, the taking of the army out of politics, had perforce to be abandoned, and Gen. Manuel Pavía y Rodríguez de Alburquerque quelled the risings in Andalusia. Castelar, reintroducing conscription, provided the means of reducing Cartagena and pursuing the war against the Carlists with vigour. When the *Cortes* reassembled in January 1874 the extreme parties voted against Castelar, whereupon Pavía, then captain general of Madrid, forcibly dissolved the *Cortes*. The federal republic was dead. A unitary regime followed, under General Serrano, until, in December 1874, another army *pronunciamiento* restored the Bourbons. Alfonso XII (*q.v.*; 1874–85), 17 years old and till then at school in England, landed at Barcelona on Jan. 9, 1875. (W. C. An.; R. S. Ll.).

K. The Later Bourbons, 1875–1931

Alfonso XII (1875–85).—National exhaustion and disillusion caused a substantial rallying of the nation around the young king. Pacification, military and political, was his first concern. The Carlists were not finally quelled until the beginning of 1876, when a general amnesty was balanced by the forfeiture by the Basque provinces of their differential system of taxation and military service. Part of the large army thus released was then sent to Cuba, where after a further 18 months of fighting the insurgents accepted the Convention of El Zanjón (Feb. 12, 1878). Arsenio Martínez Campos, Spanish commander in chief, was made governor-general and offered the island the prospect of reforms, including a more liberal tariff and eventual self-government.

Alfonso's first premier, the conservative Antonio Cánovas del Castillo (*q.v.*), ruled at first dictatorially without the assistance of Parliament. Royal decrees set aside most of the legislation and reforms of the previous regime, respecting only—for a while—universal suffrage, on which basis a new *Cortes* was convoked in 1876. The constitution of that year was a compromise between that of 1845 and the more democratic principles of the charter of 1869; it was to remain in force for 47 years. By it the franchise was limited to taxpayers; the Senate became in part elective; religious dissidence was tolerated though not recognized; and a considerable freedom of association was granted. Constitutional guarantees might, however, be suspended when the security of the state so demanded, a provision that left a tempting reserve of power in the hands of the crown, while the parallelism of civil and military districts facilitated its invocation.

The Liberals under Práxedes Mateo Sagasta formed the Fusionista Party, whose name was indicative of its heterogeneity. But the real opposition came from the Socialist-Republican left. From the founding in 1869 of a Spanish section of the First International, labour organization developed rapidly. The split between Karl Marx and Mikhail Bakunin at a congress of the International in 1872 was reflected in Spain on a regional basis, labour being predominantly Marxist in Castile and Anarchist in Catalonia. Regionalism, likewise at its most active in Catalonia, provided another outlet for political dissatisfaction with Madrid.

Cánovas' first administration lasted till February 1881, when, under suspicion of heading the country once again toward absolutism, he gave way to Sagasta and the Liberals. Thereafter, to the end of the century, the two parties alternated in power on an agreed rotatory system based on "made" elections that soon became one factor in the gradual discrediting of the restored monarchy. In August 1883 an attempted republican rising, though soon quelled, led to the discovery of widespread revolutionary activities throughout the country. Fifty Republicans were returned to the *Cortes* at the general election of March 1893. In the country at large the last two decades of the 19th century were scarred by an increasing resort to direct action and crimes of violence, with corresponding waves of harsh official repression.

Alfonso's first wife, his cousin Mercedes, daughter of the duc de Montpensier, had died in May 1878, five months after the wedding. His second marriage (1879) was with María Cristina II (*q.v.*), a second cousin of the Austrian emperor Francis Joseph. On Nov. 25, 1885, Alfonso died, leaving two daughters. Six months later on May 17, 1886, a posthumous son, Alfonso XIII (*q.v.*; reigned 1886–1931), was born. The queen was proclaimed regent.

Regency for Alfonso XIII.—The regency began with five years of Liberal rule, marked by the civil code of 1889, another major step in the consolidation of the country's still heterogeneous legislation, by the restoration of universal suffrage and of trial by jury, and by a liberalizing of the laws affecting the right of association and the liberty of the press. Attempts to curb the political proclivities of the Army were less successful and added military to Conservative opposition. The elections of 1890, which returned the Conservatives to office, showed that very few of those lately enfranchised had voted; they showed also that the home office's control of the voting continued as before.

Cánovas now based his economic policy on protection, completely reversing the moderate free-trade policy which had been so beneficial to Spanish foreign trade since 1868. Heavy increases in duties on agricultural imports, particularly on breadstuffs, and the denunciation of all treaties of commerce that contained most-favoured-nation clauses soon made their adverse effects felt and evoked loud protest. Industrial interests alone benefited, and imports of raw materials, notably chemicals, coal, and coke, increased. In 1892 Cánovas admitted that never since the restoration in 1875 had the budget been balanced and that the exchequer was bankrupt. Political bankruptcy could be seen further in the failure of both parties to tackle the problem of the *latifundios* and a land-starved peasantry. Signs of labour unrest multiplied, chiefly in Catalonia.

Morocco and Cuba.—The Rifi tribes bordering the Spanish zone in Morocco had been a continual source of trouble. In 1894 an incursion into Spanish territory resulted in defeat for the Spanish forces and a severe shock to public opinion at home. An army of 25,000 men, with 30 generals, was sent to Melilla, but hostilities were averted for the time being by a treaty signed in Fès and by the sultan's agreement to pay an indemnity of 20,000,000 pesetas. Earlier, between 1884 and 1886, Spain had established dominion

over the vast territory of Río de Oro, south of Morocco, in furtherance of a new African policy of pacific penetration advocated by the influential jurist and economist Joaquín Costa.

The position in Cuba had again grown threatening, and press censorship left Spanish opinion unprepared for its outcome. Cuban autonomist deputies in the *Cortes* had formally tabled the demand for home rule in 1878, but this was rejected, as was a Conservative measure of 1893 for political and administrative reforms tending in that direction. In 1895 a much weaker Cuban Reform Bill was passed by all parties, but before it could be promulgated a separatist rising had broken out near Santiago de Cuba, backed by a strong body of sympathy in the United States. Sagasta dispatched a preliminary force of 12,000 men to reinforce the 15,000 Spanish troops already in the island, and Cánovas, succeeding once more to the premiership (March 1895), insisted that submission must precede any concessions. Gen. Valeriano Weyler y Nicolau (*q.v.*) applied himself to the stamping out of disaffection with a ruthlessness which brought repeated diplomatic representations from the United States, which at the same time was supplying the rebels with arms.

Realizing the danger of more direct U.S. intervention, Cánovas presented to the *Cortes* a bill granting Cuba a substantially enlarged autonomy. His assassination by an anarchist on Aug. 8, 1897, brought Sagasta back into office. Recalling Weyler from Cuba, Sagasta hastily enacted conciliatory legislation and sought to propitiate the United States, even offering a treaty of commerce which would have allowed the U.S. every advantage in trade with the West Indies possessed by Spain itself. But things had already gone too far, both in Cuba and in the United States, where public opinion pressed irresistibly on Congress and president alike.

Spanish-American War.—On Feb. 15, 1898, in circumstances never clearly established, the U.S. battleship "Maine" blew up in the port of Havana, and events moved quickly to a crisis. Spain appealed to courts and governments and to the pope for mediation, but none was disposed to go beyond mild representations to Washington. In April Pres. William McKinley approved a resolution demanding the cessation of hostilities in Cuba with a view to evacuation by the Spanish forces. Sagasta gave the U.S. minister in Madrid his passports and severed relations with the United States; the known inadequacy of Spain's resources for a struggle could not prevent it from yielding to the urge to defend the last remnants of its colonial empire.

The sequel is soon told. The Spanish fleet in the Far East was defeated in Manila Bay (May), the Caribbean fleet was destroyed off Santiago de Cuba (July), and all communication between Spain and the colonies was severed. Within a fortnight of the landing of a U.S. force near Santiago the Spanish garrison surrendered (July 17; *see* SPANISH-AMERICAN WAR). At the end of July Spain sued for peace. The agreement of Aug. 9 stipulated clearly that Spanish rule in the new world must be considered at an end; and by the Treaty of Paris (Dec. 10, 1898) Spain renounced unconditionally all sovereign rights over Cuba and Puerto Rico and ceded to the United States, in consideration of a payment of $20,000,000, the Philippine Islands, the Sulus, and the largest of the Marianas. The Carolines and a few other Pacific islands were sold to Germany in 1899, and two islands omitted in the Treaty of Paris were purchased by the United States in 1900. Apart from holdings in North and West Africa, the Spanish Empire was at an end.

The Reaction in Spain.—The Liberal government was held responsible for the debacle; but the seeds had been sown long before, and the change to a Conservative cabinet was the least significant among its consequences. From the mood of sober analysis and heart-searching that ensued there emerged the "generation of '98," a group of thinkers who through their chosen medium—the essay—effected a renovation not merely of literature but of the country's intellectual life (*see* SPANISH LITERATURE). The debate on the country's role in history led to a cleavage between *europeizantes* and *africanizantes;* it led also to a new interest in Africa as the one remaining field of overseas activity. With the radical reduction of its commitments the Army became top-heavy, at once an intolerable drain on the nation's economy and more prone than ever to meddling in politics. The wave of solidarity with Spain that swept through Latin America went far to neutralize remaining antagonisms in this sphere.

Long-due reforms in taxation and the servicing of the nation's debts were carried through by a vigorous Conservative minister of finance, Raimundo Fernández de Villaverde. Bondholders were called on for even heavier sacrifices than taxpayers, and the interest on colonial debts, like that on internal debts and on Spanish holdings of external debts, was made payable in pesetas. But in the main the political scene remained untouched by the new spirit. Sagasta, premier once more in March 1901, was confronted by two major problems. One was the growth of the religious orders and congregations, in defiance of the Law of Associations of 1887 by which all congregations were required to register their members and, when not specifically recognized under the concordat of 1851, to apply for authorization. A proposal now to enforce the law greatly incensed the church. The papal nuncio announced that Rome would only consent to discuss the question on condition that all requests for authorization would be granted. To avoid a crisis just when the young king was about to become of age, Sagasta accepted a *modus vivendi.* A final settlement was not reached with the Vatican until 1912.

Industrial unrest constituted a more pressing peril. Fomented by socialist agitation and by anarchist direct action, it led in January 1902 to serious riots in Barcelona and Saragossa and on Feb. 16 to a general strike in the former city. General Weyler's methods in restoring order all but brought the government down. They provided no solution to anarchism, which under the influence of Georges Sorel was now moving toward syndicalism as a basis for organized opposition to all government as such.

Personal Government of Alfonso XIII.—Alfonso XIII was enthroned on his 16th birthday, May 17, 1902. He was still then under clerical and reactionary influences, and his contemptuous treatment of ministers showed from the beginning an intention of intervening actively in politics. His first official act was to countermand a decree closing the military colleges, aimed at reducing the disproportionate officer strength of the Army. Sagasta died in 1903. Conservatives and Liberals alike were now suffering from weakened leadership, and there ensued a period of instability and frequent changes of government.

A tendency to disintegration in the political parties was symptomatic of the growing subordination of national to sectional interests. It became an important factor in the eventual collapse of representative government. This political instability contributed to the general unrest; and the old antagonisms, born of the conflict between the industrial north and the agricultural south and of the now traditional cleavages over regional, social, and religious issues, were increasingly complicated by labour agitation. The notorious Law of Jurisdictions of 1906, under which attacks on officers and military institutions were to be tried before military tribunals, was a serious capitulation of the civil authority, that had far-reaching consequences.

Alfonso's marriage on May 31, 1906, to Victoria Eugénie of Battenberg, princess of Great Britain, marked a stage in his emancipation from clerical-conservative tutelage. Ecclesiastical controversy again loomed large at this period, formal recognition of the validity of civil marriage arousing such agitation among the clergy that the government threatened the bishop of Tuy and the Córdoba chapter with prosecution. A new Law of Associations in 1906 brought the Liberal Party itself to the verge of disruption, and after three changes of premiers the Conservatives returned to power in January 1907 under Antonio Maura y Montaner (*q.v.*).

Maura (1907–09).—Maura, who had already been premier (1903–04), had many qualities of leadership. A sincere Catholic, though no clerical, he pursued first the maintenance of order and the reform of local government. A bill to the latter end was submitted to the *Cortes* in October 1907. Aimed at destroying the power of the *caciques* (local bosses) and at educating the electorate in their privileges and responsibilities, it made voting compulsory, abolished official interference with the polls, and increased considerably the responsibility of local elected bodies. The bill met with strong Liberal opposition because of its alleged re-

gionalistic tendencies and, though finally approved by the lower house in February 1909, did not reach the statute book.

The elections of 1907 were notable for the return of a strong republican minority and the striking victory of the Solidaridad Catalana, a fusion, resulting directly from the opposition to the Law of Jurisdictions, of seven Catalan parties in defense of regionalist interests. Of the 44 seats allotted to Catalonia, 41 were gained by its candidates. Maura, ruling rather as an enlightened despot than as the head of a constitutional government, was concerned also to strengthen the Navy, to reform and to reconstruct the police force, to institute industrial tribunals, and to regulate the conditions of work of women and children.

Trouble long brewing in Morocco broke out in July 1909 with an attack by Rifi tribesmen on Spanish railway workers. The need to reinforce the Spanish troops in Africa had for some time been apparent, but Maura had hesitated to lay the necessary estimates before the *Cortes*. The proposal now of the war minister, Gen. Arsenio Linares, to organize a new field force by calling out the reserves, with its vivid memories of the useless miseries of earlier overseas expeditions, provoked another general strike in Barcelona; and a movement at first directed against "conscription" rapidly developed into a revolutionary attack on the established order in church and state that spread to the whole province. Churches and convents were favourite targets for violence. In Barcelona the rising was suppressed after three days of street fighting (July 27–29).

On July 28 martial law was proclaimed throughout Spain, and a military reign of terror continued until the end of September. In the fortress of Montjuich in Barcelona were imprisoned not only rioters but many others, notably journalists, critical of the government. A sensation was caused by the arrest of Francisco Ferrer, a theoretical anarchist well known in many countries for his anticlerical educational work and especially as the founder of lay schools in Spain. Ferrer was tried by court-martial and shot (October). The execution aroused widespread indignation throughout Europe and produced a ministerial crisis in Madrid. The government, already weakened by a reverse in Morocco (Sept. 30), was furiously attacked by the Liberals under Segismundo Moret y Prendergast at the opening of the *Cortes* in October, and Maura resigned.

Moret and Canalejas (1909–12).—Moret, who now became premier, sent General Weyler back to Barcelona to keep order, released most of the Montjuich prisoners, reduced the forces in Morocco, and reopened negotiations with Rome for a modification of the concordat. In February 1910 Moret was forced to resign through the king's refusal to grant him a dissolution, and José Canalejas y Méndez (*q.v.*), the outstanding Liberal of his day, took office. His government, "inspired by the universal spirit of liberty of conscience," tackled the continuing refusal of the religious houses to comply with the law (in respect of registration and the payment of taxes when engaged in industry and commerce) and announced measures both to restrict the number of religious houses and to implement the religious toleration enshrined in the constitution. A violent Catholic agitation resulted, 72 Spanish bishops and archbishops presenting a formal protest to the government. To attacks from the Vatican Canalejas retorted with the famous "Padlock Law" at the end of 1910 forbidding the settling of further congregations in Spain until a revision of the concordat should have been agreed on with Rome.

On the Vatican's demanding that all the obnoxious measures be rescinded as a preliminary to negotiations, the Spanish ambassador to the Vatican was recalled. Hints were dropped in papal circles of a possible *rapprochement* with the Carlist claimant to the throne, and diplomatic relations were not restored until 1912. The overthrow of the monarchy in Portugal on Oct. 5, 1910, and the expulsion thence by the new republican regime of all religious congregations did not ease the government's difficulties.

French activities in Morocco at this time compelled Spain to adopt a more active policy in its zone. To counterbalance the French entry into Fès (1910) a Spanish force was landed at Larache in June 1911 and took Alcazarquivir and Arcila. The recruiting of native regiments under Spanish officers did something to lessen popular indignation at home. France was prevented from reacting strongly by the crisis resulting from the appearance off Agadir in July 1911 of a German gunboat to "protect German interests," but tension with Spain continued and pervaded the negotiations for a Franco-Spanish agreement. Concluded on Nov. 27, 1912, the treaty reduced the Spanish zone for the third time in 12 years.

A general railway strike in Spain in the middle of 1912 threatened the country with chaos. Canalejas met it by drafting railway workers into military service and compelling them to continue at their posts as soldiers. Such firmness was balanced by a genuine readiness to understand legitimate grievances, which led the Catalanists to make a serious attempt to come to terms. The premier responded by introducing a bill of *mancomunidades* (commonwealths) whereby the four Catalan provincial councils might combine in one joint body (*mancomunidad*) to which the state would grant a substantial measure of devolution. The bill, which was inevitably unacceptable to many Liberals and Conservatives alike, and was regarded in Catalonia as merely a first installment of Catalan demands, had not passed the *Cortes* when, on Nov. 12, 1912, Canalejas too was assassinated by an anarchist.

The Parties in Decline.—The new premier, Alvaro de Figueroa y Torres, conde de Romanones, was natural heir to the Liberal leadership, but he was unable to maintain the firm party discipline of his predecessor. He pursued meantime Canalejas' policy of seeking to attract and absorb the more moderate wing of the republican left. Alfonso himself recognized the need for such an accommodation, and the response of Republican leaders like Melquíades Alvarez led to hopes that the disintegration of the regime might yet be checked.

These hopes were dashed, first by an internal crisis in the Liberal Party over the bill of *mancomunidades*, then by the "implacable hostility" proclaimed by Maura against any policy of collaboration with the antidynastic parties. With the resignation of Romanones in October 1913 the king realized that the Liberal policy which he had consistently followed since 1909 was at an end. Maura's views aroused, however, such intense popular resentment that Alfonso entrusted responsibility instead to his fellow-Conservative Eduardo Dato Iradier (*q.v.*), a choice that initiated the disintegration of the Conservative Party in its turn.

The tangled fate of the bill of *mancomunidades* was resolved, against Dato's judgment, by a royal decree of Dec. 18, 1913, that granted to the four Catalan provinces the right to group together for "exclusively administrative purposes within their competence." This and several similar royal decisions in military matters, which savoured of unconstitutional action, created considerable opposition to the government. But internal difficulties were soon to be merged in the all-absorbing preoccupations and repercussions of World War I.

World War I.—The international situation of Spain at the outbreak of war in 1914 was determined officially by the agreement between Spain, France, and England signed at Cartagena in 1907 and confirmed in conversations held there in 1913 between the French president Raymond Poincaré and Romanones, which stipulated that, "should new circumstances arise tending to alter the territorial *status quo*" in the Mediterranean or on the Atlantic coasts of Europe and Africa, the three powers would "enter into communication" in order to take any necessary measures.

The war was obviously such a circumstance. France and England made no move, but Dato promptly declared for absolute neutrality, Spain having no stake in the conflict. As for the nation, its sympathies were divided. The working classes, most of the intellectuals, and the trading communities—the Liberal left—were pro-Ally. The clergy, most of the Army and the bureaucracy, and the "idle rich"—the Conservative right—were pro-German. But there was agreement on the one essential of avoiding war, and the *Cortes*, resuming its sittings on Oct. 30, 1914, unanimously endorsed the government's decision.

A debate on military reforms brought Dato's government down in December 1915, and Romanones again formed a Liberal ministry. By then the country was profiting from industrial activity on the Allied account, the peseta appreciated, and the foundations

were laid for the repatriation of the foreign debt. This favourable picture had its reverse side, however. In Morocco military operations were again necessary, this time to defend the mines from hostile tribes, while Spanish shipping was victimized by a ruthless German submarine campaign. By September 1916 Spain had lost more than 80,000 tons, 30,000 by torpedo attack. When, on Jan. 31, 1917, Germany intimated an "absolute blockade" of the Allied coasts, Romanones delivered a spirited answer intended partly to test public opinion.

His resignation on April 19, which cost him the leadership of his party, was not solely the result of the nation's failure to rise to his lead. Toward the middle of 1916 the Army had begun to organize secretly its so-called *juntas de defensa* in furtherance first of its professional efficiency, second—and soon chiefly—of its traditional prerogatives, the threat to which came principally from the king's fondness for personal intervention. Before long they were presuming to dictate to the government in a manner which led Romanones to attempt their dissolution. But this new menace to authority from the one bulwark of order loomed larger with each endeavour to exorcize it, and Romanones chose to resign. Under his successor, Manuel García Prieto, an order to arrest the leaders of the juntas provoked an ultimatum (June 1, 1917) that brought the new government down; and Dato, recalled to office, capitulated before them, conceding to their regulations the force of law. This victory of a movement revolutionary in essence encouraged at first, in a public not alive to its implications, hopes of a renovation of political life. Coupled with early reports of the Russian Revolution, it stimulated the ferment at work in the country, and political manifestoes asking for a "renovation" in government and constitution followed one another (Socialists June 12, Catalanists June 16, left coalition June 16).

In the teeth of government opposition, an assembly of senators and deputies convoked in Barcelona formally demanded constitutional reform and set up three commissions to report to a second meeting in Madrid. This movement, which might conceivably have provided the renovation so urgently needed, was defeated by the resort to direct action of extreme labour elements. On Aug. 13, three days before the planned second meeting, a revolutionary general strike broke out, led this time by the Socialist General Union of Labour (U.G.T.) of Madrid and aimed openly at establishing a socialist democratic republic, which soon threatened to paralyze the whole country. A state of war was again declared. The Army now showed its true colours and put down the strike by machine guns, and the juntas remained the only real force left in the country.

Among the victims was the constitution. The new minister for war imposed on the king by the juntas, Juan de la Cierva, dominated a heterogeneous ministry of Maurists, Liberals, and Catalanists. The shortness of its life (November 1917–February 1918), in spite of Army support, showed that a severe blow had been struck not merely at party government but at cabinet government. Brought down by a telegraph strike, it was followed by a hiatus that only ended when Alfonso, at a midnight meeting of former premiers at the palace on March 21, constrained them under threat of abdication to form a ministry of all the talents, under Maura. This lasted till Nov. 6. The end of World War I in the same month had a natural accompaniment in the return of the Liberals to power, first under García Prieto, then (Dec. 3) under Romanones, whose first act as premier was to visit Pres. Woodrow Wilson in Paris.

The Postwar Situation.—Spared the war, Spain had passed nonetheless through a very disturbed and anxious four years. The submarine war cost it 65 vessels, in all 140,000 tons, which Germany had agreed to indemnify on a ton-for-ton basis. Against this, the influx of capital went far to revolutionize its economy. Gold reserves in the Bank of Spain, £22,680,000 in 1914, had risen to £88,920,000 in 1918. Not merely was Spain able to resorb in large part its foreign industrial debt and almost all of its national debt and to acquire the ownership of the railways, but also new industries had been founded, not all of which disappeared with the return of peace, and in older industries (such as the Basque iron and steel works) plant and conditions were modernized. A mingling of two political currents, one a democratic and constitutional agitation born of the Allied victory, the other a revolutionary agitation akin in the civil sphere to that of the *juntas de defensa* in the military, created an involved situation in Barcelona which resulted in the spring of 1919 in open conflict between the military and the civil authorities. When the former expelled the latter from the town, the failure to take up so flagrant a challenge brought the government down, and again there ensued a period of cabinet instability. Its most notable feature was that "made" elections, the mainspring of the old system, were failing now to produce the desired majorities. On March 8, 1921, Dato, who had been engaged in trying to rebuild Conservative unity, was assassinated.

The murder accelerated the final disintegration of the rotatory system which, ever since the death of Alfonso XII, had served the monarchy as substitute for a real constitutional regime on the English model. To its own internal weaknesses was added a triple assault from outside. There were the antidynastic elements, once grouped together under the common label of Republicans, now moving toward socialism on the one hand and toward different varieties of syndicalist or anarchist revolution on the other hand; there were the Catalan home rulers, gradually evolving from autonomy toward separatism under the stimulus of the respect shown by the conference at Versailles for the principle of self-determination; and there was what might be called the military syndicalism embodied in the defense juntas.

With the last-named, governments lacked the moral courage to deal; toward the violence so frequently associated with the first they opposed more violence, failing to recognize legitimate grievances where they existed and tending always to identify the employers' interests with those of authority. To Catalanism, opposition in Madrid was instinctive, and the failure of a new approach from Barcelona in 1918–19 did much both to strengthen and to unify support for the movement throughout Catalonia. By 1923, when two strong groups, Estat Català and Acció Catalana, of the right and left respectively, were in agreement on the main objective and had concluded a triple alliance with Basque and Galician autonomists, it was clear that this issue was destined to loom larger and larger in the country's politics.

War in Morocco.—Effective occupation and pacification of the Spanish zone in Morocco were still far from complete, and in guerrilla warfare the tribesmen were often more than a match for Spanish troops, with whom service in Morocco had become notoriously unpopular. In 1921 Manuel Fernández Silvestre, in command at Melilla, embarked impulsively, with Alfonso's personal backing, on an operation which ended in crushing disaster at Anual (July 21). To heavy losses in men and matériel was added a forced withdrawal from the whole eastern zone, the fruit of 12 years of slow penetration. General Fernández committed suicide.

The repercussions in Spain were profound. The government fell, and Maura was called on in August to face the emergency. An army of 140,000 men was sent to the rescue of the troops in Morocco. To the growing public demand for an inquiry the new government had at length to give way, and General Picasso was charged with investigating the responsibility for the disaster, his report being submitted in due course to a committee of the *Cortes*. Meanwhile the *juntas de defensa* had reacted strongly with a campaign of threats and accusations against the *Cortes*, which they sought to hold responsible for the general disorganization underlying the Moroccan crisis. The government retorted with a formal disbandment of the juntas, replacing them by *juntas informativas* subject, in theory at least, to the minister for war. But the juntas were the stronger, and in March 1922 Maura was forced from office. His successor, another Conservative, José Sánchez Guerra, was brought down in December by the debate in the *Cortes* on the Picasso report. The insistence in Socialist sectors of opinion that definite responsibilities attached to specified individuals and should be brought home to them charged the issue with high explosive.

A Liberal coalition followed and was confirmed in office at the general election of April 1923. The sensational feature of this was the return of Socialists for five out of the seven seats in Madrid, a success attributed by their party to the strong line that it had

taken on the war in Morocco. The burden which the Moroccan problem imposed on the exchequer (an average of 358,000,000 pesetas annually in 1919–23 as compared with 75,000,000 pesetas for 1909–13 and 146,000,000 pesetas for 1913–19) was aggravated by the gradual wilting of the artificial prosperity of the war years and recurrent industrial troubles at home. For the most part, however, these problems were but facets of the basic inability of government after government to uphold the prestige of authority. In the 21 years since Alfonso's accession to the throne there had been 33 ministries.

Dictatorship of Primo de Rivera (1923–30).—In September 1923 the report of the *Cortes* commission on the Anual disaster was ready. Several politicians were believed to be deeply involved, some as having abetted the king in his fondness for unconstitutional initiative. The reaction of the Army, notoriously restive under parliamentary or civilian criticism, was awaited with some concern. Suddenly, on Sept. 13, a dramatic stroke from this quarter brought to an end the system under which the country had lived since 1875. The captain general of Catalonia, Miguel Primo de Rivera (*q.v.*), marqués de Estella, rebelled against the government from his headquarters in Barcelona, rejecting its authority and threatening its members with jail. His manifesto declared it imperative to liberate the country from "the professional politicians, the men who for one reason or another are responsible for the period of misfortune and corruption which began in 1898 and threatens to bring Spain to a tragic and dishonourable end." "The wide net of greedy politics," he added, "has caught and imprisoned in its meshes the royal will itself." He announced the setting-up of a military directorate which would find for the Moroccan problem a "quick, dignified, and sensible" solution and which would bring home responsibility promptly and justly by the formation of tribunals "of recognized moral authority."

The premier proposed to the king strong action against the rebels, who included now the military authorities of Bilbao and Saragossa and a council of high officers in Madrid. The king asked for time for reflection, and the government resigned. Two hours later a deputation of generals was received at the palace and the king requested Primo de Rivera, who was still in Barcelona, to take office. Administratively the new directorate struck an original note in that the only minister was Primo de Rivera himself, ministerial departments being left in charge of permanent officials while the "directors" concerned themselves with specific problems as they arose. The one significant exception was the home office, which was entrusted to Gen. Severiano Martínez Anido with the rank of undersecretary of state. Public opinion received the *pronunciamiento* without demonstration, save for a protest from the Socialist Party. The directorate declared the country to be in a state of war. A strict press censorship and a ban on political manifestations were imposed. The *Cortes* was dismissed, and the seizure of the files of the Commission on Responsibilities, shelving the further inquiry into the Moroccan disaster which was due to begin on Sept. 15, made clear the reason for the timing of the coup. When, two months later, the king refused to acknowledge his obligation under the constitution to convoke a new *Cortes* within three months of a dissolution, he made equally clear his personal responsibility in the collapse of the parliamentary regime and rendered it inevitable that the eventual fall of the dictatorship should involve that of the throne. In November king and dictator paid an official visit to Italy and expressed open admiration of Fascism.

The compelling problem was still Morocco, and it was there that the dictator won his greatest success and the nation's gratitude. The first phase, initiated in the summer of 1924, was one of cutting losses and retreating to a base line near the coast sufficient to cover Ceuta and Melilla. Primo de Rivera claimed later that in this he was interpreting the popular will, "which was weary and sceptical of any other possible solution." He himself led the operation in the field. It evoked opposition from the Army and was not effected without heavy loss, but by the end of the year it was completed.

The sudden attack of Abd-el-Krim (*q.v.*) on the French protectorate in 1925, which led to combined action by France and Spain against the rebellious tribes, made possible a complete reversal of policy. The brilliant landing (Sept. 8) in Alhucemas Bay, again led by Primo de Rivera in person—the other generals having refused—was a thrust at the heart of the enemy's power, and within a month Abd-el-Krim was in flight. The pacification of the entire Spanish zone was not completed until 1927, but already Spain's position and prestige in Africa had been retrieved.

Primo de Rivera was now tempted to consider his mission at an end and withdraw, but there was substantial popular support for the view that the dictatorship could contribute no less to the solving of the nation's internal difficulties. He decided, however, that the military directorate had by now served its purpose and, replacing this in December 1925 by a predominantly civilian cabinet, sought to base his regime on more normal political foundations. The Unión Patriótica (1926) was an attempt to form a nonparty organization of all such good citizens as would accept his own motto of "Country, Religion, Monarchy"; the "supreme national assembly" (September 1927) represented a pseudo *Cortes* largely nominated by the dictator and given a merely advisory function.

Primo de Rivera remained the fount of power and, in his zeal for reform, was driven inevitably to abuse that power, both by attempting to force the pace and by riding roughshod over dissident susceptibilities. His successes lay accordingly in such spheres as public works, finance, and public order. In the conciliation of opposition elements he failed to make headway. The Confederación del Ebro, associating the many interests concerned in the utilization of that river, was a notable innovation and the forerunner of others of the same nature. Ambitious schemes for the electrification of the railways and for road development were set in motion. Income tax was introduced in December 1926 and gradually worked its way into the national finances. Morocco had ceased to be an intolerable drain on the exchequer, and in 1927, for the first time in 20 years, no loan was raised. Economic policy was directed to the correction of the heavy adverse balance of trade by stimulating home industries, canalizing investment, and creating state monopolies. In the labour field an elaborate system of corporations was initiated; deriving from the Italian model, it won the approval of many Socialist leaders. An agrarian credit bank gave promise of new life to the small farmer; the other great problem in agriculture, the breaking-up of the *latifundios* (large estates), the regime left untouched.

In 1925 the government undertook the reorganization of provincial and municipal administration. The right to levy certain rates was delegated to municipalities, with a corresponding widening of their range of action; and female and proportional suffrage were instituted in local elections. One important provision in the decree of provincial reform was the abolition of the *mancomunidad*, the central body in Barcelona responsible for coordinating the work of Catalan local councils. In its Catalan policy the directorate had soon reversed the sympathetic attitude to autonomy voiced in Primo de Rivera's first utterances, which were evidently directed to winning support in Catalanist circles for his *coup d'état*. Army opposition to any measures of Catalan devolution combined with the inherent logic of dictatorship to create an attitude and a policy described in Catalonia as one of systematic persecution.

In external relations interest centred chiefly on the League of Nations. In 1926 Spain claimed a permanent seat on the council of the League in fulfillment of repeated promises by the French and British governments. Similar claims by Brazil, Poland, China, and Persia and opposition from Germany, Sweden, and others to any increase in the number of permanent seats led to a confused situation and to much resentment in Spain. At the June meeting of the council Spain's representative was ominously absent, and on Aug. 9 Spain signed a treaty with Italy stipulating mutual neutrality in the event of unprovoked aggression. Further to stress this independent mood, Primo de Rivera announced in August his desire for such a drastic change in the statute of Tangier (1923), regulating the status of Tangier, as would have amounted to the setting up in Tangier of a Spanish protectorate. The assembly and the council of the League decided in December to institute a special semipermanent seat on the council for Spain. Spain refused this and gave notice of withdrawal from the League. Nego-

tiations with France over Tangier led finally to a number of French concessions (1928) which improved the security position in the Spanish zone of Morocco. This was a factor when, on the invitation of the president of the League council in March 1928 to reconsider its attitude, Spain announced its readiness to remain a member of the League and to accept such status on the council as the League might determine.

The year 1926 witnessed three attempts to overthrow the dictatorship by force. A military rebellion at Valencia in June, led by old General Weyler and Gen. Joaquín Aguilera, was nipped in the bud. Trouble with the artillery corps arose from a measure in July abolishing its cherished tradition of accepting promotion by seniority only as a guarantee against favouritism. A compromise settlement was, the corps claimed, broken by Primo de Rivera, and in September the artillery officers too prepared a revolt. Its failure was followed by the abolition of the corps. An amnesty later restored all but a few to their posts, but much ill-feeling remained. In November Col. Francesc Macià, exiled leader of the separatist Estat Català party, launched a futile attempt to invade Catalonia from France and set up a provisional government there for the restoration of "the national sovereignty."

By the end of 1928 civil discontent with the dictatorship had combined with Army unrest to render the dictator's position more difficult. Continual dissensions between dictator and king, riots in the universities, and protests from intellectuals were symptoms of the general unease. The world economic crisis of 1929 was soon reflected in a serious fall in the peseta. In January 1930 the finance minister, José Calvo Sotelo, resigned; and when, shortly after, the captains general of the Army intimated that they no longer stood behind the dictator his fall became inevitable. On Jan. 28, 1930, Primo de Rivera resigned and retired to France. He was already broken in health and died in Paris on March 16. (W. C. An.; X.)

Fall of the Monarchy.—A temporary government under Gen. Dámaso Berenguer now sought to prepare the way for a return to constitutional rule. Unrest, however, continued. Revolutionary strikes multiplied all over the country. The ranks of republicanism were swollen by all those who refused to absolve the king from his responsibility in the abrogating of the constitution, and a revolutionary committee, pledged to bring about a republic, concluded with Catalan autonomists the Pact of San Sebastián (Aug. 17) whereby it undertook, in return for their support, to introduce a bill for regional autonomy as soon as it was in power. The peseta, which had dropped from 29 to the pound sterling to 36.50 during 1929, fell to 51 by the autumn of 1930. An abortive military rising took place at Jaca (Dec. 15). On Feb. 14, 1931, the government resigned. A new administration under Adm. Juan Bautista Aznar was charged with convoking, first, municipal elections, and then parliamentary elections for a constituent *Cortes*, but it was understood that the former would be taken as a test on the one great issue and that, if the outcome were held to warrant it, the revolutionary committee would attempt to seize power.

Full results of the municipal elections of April 12, 1931, which went off quietly enough, were never published. The only figures issued showed that 22,150 seats had gone to Monarchists and 5,875 to Republicans. Although large numbers of Monarchists were elected in the country districts, all the provincial capitals showed Republican majorities. In Barcelona the Republicans had a three-to-one majority of votes, in Madrid, Niceto Alcalá Zamora (*q.v.*), leader of the revolutionary committee, headed the poll. Alcalá Zamora took the bold course of demanding Alfonso's abdication and the immediate transfer of powers to his committee. The king, after some parleying, agreed to leave Spain, but without formal abdication, and on the night of April 14 he embarked at Cartagena for France. The revolutionary committee became the provisional government of the Second Republic.

L. The Second Republic, 1931–36

King Alfonso's action, and the fact that the army was no longer behind the monarch, allowed the establishment of the new regime without bloodshed. But the initial optimism did not allow for long the illusion that the nation as a whole had turned to fervent belief in responsible democracy or achieved the competence to exercise it. Right-wing elements—Army, church, landed aristocracy—were prepared to tolerate the republic so long as it respected what they believed to be their prescriptive rights. Left-wing elements—Anarcho-Syndicalists and the more extreme Socialists (Communism was as yet an insignificant force in Spain)—regarded its advent as but a stage to the overthrow of the established order of society. The regional autonomists, fortified by the Pact of San Sebastián, appeared to Madrid to be intent on disrupting the national unity. Moreover, the new government, attempting to steer a middle course through all these dangers, was forced by the quantity of social problems facing it to invade sphere after sphere of vested interests. The dictatorship had been merely the culmination of a long denial to the mass of the people of education in political responsibility. The Republic found itself heir to the consequences, and the challenge to the political stature of the nation was as searching as that to the statesmanship and administrative ability of those now come to authority.

During the Republic there were a series of revolutionary strikes, anticlerical outrages, and incipient revolts against the regime, now of the right, now of the left, now of the regions of the periphery. In May 1931 churches were burned by the mobs in Madrid, Valencia, and in parts of southern Spain. The monarchist newspaper *ABC* was suspended and the primate, Pedro Cardinal Segura y Sáenz, whose anti-Republican activities were notorious, was expelled from Spain. A Communist rebellion was crushed in January 1932, a right-wing rising under Gen. José Sanjurjo the following August. The economic life of the country was seriously jeopardized by its constant subordination to political agitation.

Parliamentary elections held in June 1931 gave the left-wing parties 315 out of the 466 seats in the new constituent *Cortes*. The Monarchists had 1 deputy. The *Cortes* met in July, and on Dec. 9, 1931, the new constitution was promulgated. This defined Spain as "a democratic republic of workers of all classes," with authority "emanating from the people," and no official religion. It bound Spain to respect for the rules of international law and to the renunciation of war as an instrument of national policy. Provision was made for the granting of autonomy to regions which could justify the demand for it, but any federation of autonomous regions was forbidden. Titles of nobility were abolished. Free expression of opinion was guaranteed, and both sexes were given the vote from the age of 23. All property and wealth were declared subordinated to the interests of the national economy; forcible expropriation of property, against adequate indemnity, might be authorized by the *Cortes*. Marriage was to be founded on sex equality, and unions were made dissoluble "as a result of mutual disagreement or on the petition of either party." Primary education would be, not merely compulsory and free, as nominally under the monarchy, but exclusively secular.

Legislative authority was assigned to a unicameral *Cortes*, with four years as the maximum length of each Parliament. The president, to be chosen by an electoral college comprising all deputies and an equal number of *ad hoc* members, was to hold office for six years. His powers included the nomination of the premier and considerable authority over the *Cortes*. Amendment of the constitution required an absolute majority in the *Cortes* and the lapse of at least four years from the date of promulgation.

The most hotly debated clauses related to religion. New measures in this field included the disestablishment of the church, the cessation from December 1933 of state payment of the clergy (a form of compensation for past expropriations agreed upon in the Concordat of 1851), and the submission to a special law of all religious confessions and congregations. Freedom of conscience and of worship was recognized, subject to government sanction for all public manifestations of religion. Religious orders requiring a vow of obedience to an authority foreign to the state were to be dissolved and their property nationalized for educational and charitable purposes. Other orders would likewise be dissolved if considered a peril to the safety of the state. None might hold more property than was necessary to its sustenance, and none could engage in industry, commerce, or education. Finally, it would be "permissible" for the property of all the orders to be nationalized.

These provisions occasioned a first serious political crisis. Manuel Azaña (*q.v.*), who as war minister had been active in reorganizing the Army and reducing its officer strength, violently attacked the religious orders in the *Cortes*, announcing as the government's intention the dissolution in Spain, under the "vow of obedience" clause, of the Society of Jesus (this took effect on Jan. 23, 1932) and the application of the other clauses with the utmost rigour. When, after an all-night sitting, the clauses were approved by a half-empty house (178 votes to 59), the premier, Alcalá Zamora, and the home secretary, Miguel Maura, resigned (Oct. 14, 1931). Azaña thereupon became premier, and in December Alcalá Zamora was elected first president of the republic.

A week after Azaña's accession the surging passions constrained the government to introduce the Law for the Defense of the Republic, under which certain constitutional guarantees might be suspended at the discretion of any minister. By it the home secretary was empowered to cancel meetings, dissolve associations, close clubs, and suppress newspapers. Eleven "acts of aggression" against the republic were named, some in the vaguest terms, and made punishable with fines or exile.

Left-Wing Government (1931–33).—Once the constitution was promulgated, Azaña recast his government, which became predominantly Socialist, because of the withdrawal from it of the Radical element under the leadership of Alejandro Lerroux (*q.v.*). The chief measures of 1932 were the Agrarian Law and the Statute of Catalan Autonomy. The agrarian problem, one of the most pressing inherited by the republic, hinged on the prevalence throughout central and southern Spain of huge estates held by absentee landlords and worked by peasants at starvation wages. The new law (Sept. 15) provided for expropriation at discretion, against payment in government bonds to the value of the estate as assessed for taxation. Its administration was entrusted to a state-subsidized Institute of Agrarian Reform, representative of both owners and landworkers.

The movement for regional autonomy was strong in the Basque provinces (although not successful there until Oct. 1, 1936, after the outbreak of the Civil War); it was weaker among Galicians and Valencians, who were far less united in their claims. In Catalonia its urgency was extreme. The fall of the monarchy had been followed there by the immediate proclamation of a "Catalan state," in a manifesto envisaging a "confederation of Iberian peoples." Appeals from Madrid secured the substitution of the historic and less provocative term *generalidad* of Catalonia and resignation to the status of an autonomous region within a unitary Spain. The necessary plebiscite of the Catalan people (Aug. 2, 1931) gave a vote of 592,961 for the draft Autonomy statute and of 3,276 against. Despite considerable opposition within the *Cortes* and from various interests without, the statute, much revised, was approved on Sept. 9, 1932, by 314 votes to 24. By it the *generalidad* was empowered, among much else, to organize its own police services and be responsible for public order, to execute much state legislation, and to found and maintain its own educational institutions. Catalan and Castilian were to be "co-official" languages. Though bitterly disillusioned by the mutilations suffered by the statute, Catalonia, under its presidents Francesc Macià (*q.v.*) and —on his death in 1933—Lluis Companys, became on the whole the most contented part of Spain and the least affected by strikes and revolts. The Law of Religious Confessions and Congregations, implementing the clauses of the constitution dealing with religious activities, also had a stormy passage, lasting seven months (October 1932–May 1933). The proposal that teaching by the orders was to cease after 1933 made necessary alternative provision for the education of at least 350,000 children—an impossible undertaking. Already in June 1931, in Madrid alone, 50,000 children were without schools. The *Cortes* had authorized the creation of 27,000 new schools, 7,000 to be finished within a year; but efficient teachers could not be thus improvised. Misgivings were widespread and were shared by the president himself, who deferred signing the law until the expiry of the period allowed by the constitution.

During these two years, despite the government's efforts to cope with its many major problems, opinion had been running strongly against the left. Opposition was much exacerbated in January 1933 by the ruthless handling of disturbances in the village of Casas Viejas, near Medina Sidonia. In April partial municipal elections, held in 2,500 rural districts, gave impressive Conservative majorities. In September Azaña resigned; and, after the Radical leader Alejandro Lerroux had failed to form a government, the *Cortes* was dissolved and elections fixed for Nov. 19. In them the new female vote, totalling 6,500,000, could be foreseen as likely to strengthen any swing to the right.

Centre-Right Government (1933–35).—The election results showed how deep was the disillusion with the republican experiment to date. In the new *Cortes* the right held 207 seats, the centre 167, and the left 99. The centre thus held the balance of power, and—with occasional infiltrations from the right—governed for the next two years, generally under Lerroux. Changes of government were numerous (seven in 1935 alone). The most important, in October 1934, admitted three members of the right and precipitated revolutions in Catalonia and Asturias. In Barcelona, on Oct. 6, the *generalidad* again proclaimed the Catalan state of the federal Spanish Republic. The central government reacted strongly. After some street fighting, Companys and his fellow-ministers were arrested, the Autonomy statute was annulled in fact if not formally, and Catalonia was again ruled from Madrid. The extremist revolt in Asturias (Oct. 6–13), which resulted in 1,335 killed and 2,951 wounded, was liquidated with great severity, reprisals being taken all over Spain. It was during this period that the Falange (*q.v.;* Spanish Fascist Party) was founded by José Antonio Primo de Rivera, son of the former dictator. The right-wing leader in the *Cortes* was José María Gil Robles (*q.v.*).

Government policy during this biennium was directed broadly to obstructing previous legislation of the left until, in December 1935, revision of the constitution should become legally possible. Thus the substitution of secular for religious schools was indefinitely postponed, the clergy had part of their state stipends restored to them, the transfer of powers to Catalonia was delayed, and a new Agrarian law treated the large landowners with respectful benevolence. But as the date in question drew near it became evident that this negative policy and the severity of the government's repressive measures were in their turn producing a widespread reaction. Azaña, arrested in 1934 on suspicion after the Catalan revolt, tried, set free, and later rearrested, became a popular hero and the centre of progressive hopes, the "strong man" who would soon return to power and carry to completion the reforms already begun. Some looked on him as a possible dictator of the left. By the end of 1935 the centre-right could hold on to power no longer. The president acceded to a dissolution, and new elections were announced for Feb. 16, 1936.

The Popular Front (February–July 1936).—From the political maneuvering preparatory to the elections Azaña emerged as the leader not only of his own party but also of the group of parties and trade unions (comprising Republicans, Left Republican Union, Socialists, and Trotskyists) that now banded together to ensure electoral victory for the left. He received widespread support from the Syndicalists, Anarchists, and Communists. This Popular Front, so-called after a similar French combination, won by a substantial majority, 256 to the left (including 16 Communists), centre 52, and right 165. Soon, however, disturbances of all sorts began to occur. Officials dispossessed during the preceding two years clamoured for reinstatement; prisons were burst open; bands of peasants seized land and defied the law to eject them; churches, seminaries, monasteries, and the offices and houses of capitalists were set on fire; there was a wave of murders by gunmen. During the first four months of Popular Front rule 113 general and 218 partial strikes took place, while 170 churches, 69 clubs, and the offices of 10 newspapers were fired by incendiaries, who attempted to burn a further 284 buildings, 251 of them churches.

Politically, the event of this period was the deposition, on the charge of unconstitutional dissolution of the *Cortes*, of President Alcalá Zamora. Having tried for so long to steer a middle course, the president found himself under attack by both right and left. Azaña had gone so far as to break off relations with him. Only 5 deputies voted for the president, 238 against. On May 10 Azaña

was elected, almost unanimously, as his successor.

The new premier, Santiago Casares Quiroga, proved wholly unable to cope with the indiscipline of the country. While his government worked out fresh measures of reform, Spanish fascism grew, much as republicanism had grown in 1930–31, as a protest against the virtual usurpation of power by extremist violence. The premier flung down a challenge: "In its relations with fascism, the government is a belligerent." The challenge was taken up, and soon violence and counterviolence had relegated the activities of the *Cortes* to insignificance.

On July 13, in revenge for the murder of a Communist lieutenant in the shock troops, José Calvo Sotelo, a former finance minister of Primo de Rivera, was arrested and murdered by men in officers' uniform. Four days later an Army mutiny broke out in Spanish Morocco, led by Gen. Francisco Franco (*q.v.*), which spread next day to the mainland and within 48 hours had involved the whole country in civil war.

M. The Civil War, 1936–39

Everywhere garrisons revolted. In the south, Seville (under Gen. Gonzalo Queipo de Llano), Córdoba, Granada, and Cádiz supported the rebels; in the north, all Galicia, most of León, and part of Asturias, with Burgos (for three years the Nationalist headquarters), Salamanca, Valladolid, Segovia, Pamplona, and Saragossa. Both in Madrid and in Barcelona the mutinies failed (otherwise there might have been no war), and the government began the struggle with the whole of eastern and most of southern Spain under its control. The Basque provinces illustrated the tug of conflicting loyalties. Biscay (Vizcaya) and Guipúzcoa, setting autonomy above all else, threw in their lot with the regime pledged to secure this for them; Álava sided, as also did Navarre, with the insurgents, who claimed to have risen in defense of religion and traditional values.

The Nationalists, as the insurgents called themselves, representing that theirs was no mere *pronunciamiento* but a *movimiento nacional*, lost several outstanding men early, notably General Sanjurjo and Gen. Emilio Mola, killed in airplane crashes, and Gen. Manuel Goded Llopis, shot after the unsuccessful rising in Barcelona. They had with them, however, the bulk of the Army, the armed police, and the arsenals. The Popular Front had to rely chiefly on untrained volunteers and on such arms, outside the arsenals of Madrid and Barcelona, as the unions had been storing for their own purposes. Much time was necessary to turn improvised militias into an efficient army, and by then the Nationalists had greatly improved their positions. Casares Quiroga had resigned the premiership on the outbreak of war, unwilling to surrender to the clamour of the working class organizations for arms to be distributed to them. Azaña's choice of a moderate, Diego Martínez Barrio, was vetoed by the leaders of the extremist groups, because of the not unfounded suspicion that Barrio was disposed to treat with the rebels. He then turned to a personal friend, José Giral, the minister of the Navy in the previous government, who hastily formed another government of Republicans, with the Socialists still unrepresented. Giral proved unable to resist the pressure from the workers and on July 19 orders were given for arms to be distributed to them. It was by then too late; the rebels had already won many provinces.

By the end of July 1936 foreign intervention had begun. The Nationalists received combatants, technicians, and large supplies of war matériel from Italy and Germany, the fruit of prior consultation with Rome and Berlin. From the U.S.S.R., the All-Union Central Council of Trade Unions made the Republicans a first payment of 12,145,000 rubles; both the U.S.S.R. and Mexico began to send war matériel; extremist volunteers (mainly Communist) from many countries entered Spain and formed the International Brigade. Realizing the danger of international complications, France approached the leading powers, and as a result formal embargoes were placed on the export of war matériel and a nonintervention committee, representing 27 nations, was set up in London. Intervention continued nonetheless throughout the war.

With the capture of Badajoz in the middle of August the Nationalists were enabled to unite their northern with their southern forces; and while the former took Irún and San Sebastián early in September, the latter advanced rapidly upon Madrid. The capital was saved by the detour made to relieve the Nationalist garrison imprisoned in the Alcázar of Toledo (Sept. 27). Thanks to this delay the International Brigade was able to take up a position in strength before the arrival of the Nationalists on Nov. 6; and instead of submitting to a triumphal entry the Madrileños held out through a 28-months' siege.

ROBERT CAPA—MAGNUM

SPANISH CIVIL WAR

A Loyalist infantryman falls, fatally wounded during the 1936 attack on Córdoba

As the threat to the capital developed, the government, now under Francisco Largo Caballero (*q.v.*) and enlarged by the inclusion of both Communists and Anarcho-Syndicalists, moved to Valencia (Nov. 7), leaving Madrid in charge of a defense council under Gen. José Miaja. President Azaña had already gone to Barcelona. There the *generalidad* was allowed to retain nominal power and even to take over services reserved by the Autonomy statute to the state; but real power had passed to the unions, which collectivized industry and commerce (Oct. 28) and were responsible for the ban on public worship that only ended with the final defeat of the Republicans.

Apart from the taking of Málaga (February 1937), little was achieved by the insurgents in the winter of 1936–37, two attempts to cut the roads to Madrid conspicuously failing. In April 1937 a new and successful offensive was begun in the north, with Bilbao as its first objective. The city's "iron ring" of defenses held out for nearly two months, but on June 19 the Basque capital fell and one of Spain's two autonomous regions was again centralized. Santander was taken on Aug. 25, and Gijón, the last town to hold out in the north, on Oct. 21.

On both sides the war was marked, especially in its early stages, by a ruthlessness which astounded the civilized world. Churches were burned or desecrated, and public religious observances forbidden throughout republican Spain; ten bishops and many thousands of priests, religious, and devout members of the laity were murdered in cold blood, for no political activity or crime. The Nationalists for their part organized mass executions (*e.g.*, in Badajoz), and the Basque town of Guernica was subjected to terroristic air bombardment.

On Oct. 1, 1936, General Franco assumed the leadership of Nationalist Spain and outlined the features of his proposed "broadly totalitarian" rule. These included abolition of popular suffrage and of regional autonomy; equitable and graduated taxation; complete religious tolerance and a new concordat with Rome; in foreign affairs, suppression of all "Sovietic contacts" and preferential treatment for "nations of related race, language, or ideology." A technical council of state was set up, to be succeeded in January 1938 by a cabinet on the orthodox pattern. On April 19, 1937, the two main Nationalist groups—Falangists and Traditionalists—were fused into a single party, the Falange Española Tradiciona-

lista (F.E.T.), and all other parties were dissolved. The organization of the F.E.T. was developed four months later by the creation of a national council of about 50 members and a *junta política* or party cabinet invested with considerable powers.

Much constructive legislation was promulgated even during the war, such as the Labour Charter of March 9, 1938, which, under captions like "Work for All," "Remuneration and Security," "Protection and Production," gave the worker an undertaking, somewhat vaguely worded, that the "new state" had not come simply to restore the *ancien régime*. In agrarian policy the objective was to give every labourer a living wage and every peasant family a small holding and to improve sanitary and housing conditions in the villages. Little idea was given as yet of how such aims were to be accomplished. Another feature of the Labour Charter was the creation of vertical syndicates combining into one organism, under state direction, all the elements functioning within a single service or branch of production. This departure earned for the new regime the adjective "national-syndicalist."

The Republican cause suffered from internal differences much more fundamental than were to be found on the other side, and serious clashes occurred. A miniature civil war within the Civil War was caused by an Anarcho-Syndicalist rising that raged for a week in Barcelona (May 3–10, 1937). On this followed a major crisis in the Valencian government, leading to the formation of a new cabinet, under Juan Negrín (*q.v.*), from which the Anarcho-Syndicalists were eliminated; they were not again represented in the government until April 1938. The *generalidad* underwent numerous crises on a smaller scale (six between September 1936 and June 1937 alone), which were due also, principally, to the clash between centralizing and decentralizing groups, though, as the combat became fiercer, these drew more closely together. Large-scale plot and spy trials were frequent, some of them implicating the anomalously placed Trotskyists, whose group, known as the P.O.U.M. (Partido Obrero de Unificación Marxista) was the Cinderella of the Republican family.

By the end of the first year of war, General Franco held 35 of Spain's 50 provincial capitals and 119,690 sq.mi. of territory. But the Republicans had as yet scarcely organized their "new army," and the struggle was far from over. The loss of the north and the consequent unification of front simplified their practical problems; and when, on Dec. 4, 1937, they launched an unexpected offensive in Aragon, it won them the city of Teruel (Jan. 9, 1938). This was to be their last, as it was almost their first, important gain and was lost once more on Feb. 22. With the spring the Nationalists regained the initiative, relieved Huesca, penetrated into Catalonia, captured Lérida (April 3), and pursued the enemy up the Segre Valley to Tremp. An almost simultaneous push farther south carried them to the Mediterranean (April 15), and soon they had carved themselves a corridor 40 mi. wide, threatening Castellón de la Plana to the south and Tortosa to the north. Republican Spain was thus cut in two, and its government, which had removed from Valencia to Barcelona on Oct. 31, 1937, deputed General Miaja, the defender of Madrid, to act as civil and military governor of its central and southern territory.

International Activity.—The efforts made by the London Committee to prevent, or at least to lessen, foreign intervention were many and complicated. Though the entry of foreign combatants was made illegal (Feb. 21, 1937), they continued to enter, despite a coastal control system inaugurated on March 7. All the powers save Great Britain and France soon withdrew from this, and Great Britain proposed its supersession by port control and by the granting to both parties of belligerent rights as soon as the withdrawal of foreign combatants already in Spain should have made substantial progress. In fact General Franco never withdrew more than 10,000 of these during the war, and the Republicans, though more amenable, had not completed withdrawal at its close. Belligerent rights were, therefore, never granted.

In the summer of 1937 intensified pro-Nationalist submarine warfare in the Mediterranean led to a nine-power conference being held at Nyon, Switz. This organized (Sept. 14) a new system of maritime zone patrols and agreed that any submarine attacking a non-Spanish merchant ship should itself be attacked. As the fighting moved more and more toward eastern Spain, attention became increasingly centred on the bombing of Mediterranean ports, which often resulted in great damage to neutral shipping and much loss of life among civilians. Protests were made by several powers and by the Vatican against the repeated bombing of open towns (Granollers suffered 700 casualties in one air raid, and Falset, near Gandesa, was almost completely destroyed).

The idea of peace negotiations, which the powers would have supported, was rejected throughout by General Franco, who insisted on the unconditional surrender which he eventually obtained. Signs that the Republicans were envisaging defeat first came in April 1938, when Negrín formulated 13 points as his irreducible minimum. At the time of the Munich agreement on the Sudetenland (September 1938) these were given great publicity, and there was talk of a more moderate Republican government which might canvass for an armistice. That this was not formed may have been because of a checking of the Nationalists on the Ebro (July 26–Nov. 18, 1938), which gave the Republicans new hopes. These proved vain. Their Army was exhausted, their people half-starved, their territory cumbered by about 3,000,000 refugees from the west. When at length the Nationalists were able to recross the Ebro, even the severe winter could not hold back their final sweep to victory.

The End of the War.—The war had been one of lightning offensives and wearisome delays, and it conformed to type to the end. The last great offensive began on Dec. 23. A general advance in Catalonia soon developed into an attack on Barcelona which, menaced from both northwest and southwest, fell on Jan. 26, 1939, after a campaign of only 34 days. The government fled north to Figueras, where, on Feb. 1, 62 members of the Republican *Cortes* held a meeting in the castle vault and Negrín hurled defiance at the enemy, while announcing that his 13 points were now reduced to 3. Pursued northward along the three main roads to France, the Republican forces soon lost the rest of Catalonia. Hundreds of thousands of refugees poured into France, able-bodied men of military age being at first sent back, though eventually admitted and interned. When Gerona fell on Feb. 4, the government moved to a village near the French frontier. Across this, a day later, passed a succession of presidents: Azaña, Companys, and the Basque president José Antonio de Aguirre.

On Feb. 28 Azaña resigned, Negrín and his cabinet returning to Madrid to continue the struggle, while the Nationalists prepared to move south to attack the capital. With no heating in the city, only two ounces of food daily, and hundreds dying of starvation, attack proved unnecessary. On March 5 all parties except the Communists formed a new council of defense, again under General Miaja, ousting the Negrín government. A revolt against the council by Communist and other Negrín supporters broke out two days later but was suppressed after a week of heavy fighting, and the council addressed itself to preparing for surrender. On March 28, without resistance, 200,000 Nationalist troops marched into the capital. By the following day the rest of Republican Spain had surrendered, and Burgos radio announced that the Civil War was over. It had lasted two years and 254 days and was estimated to have cost 1,000,000 lives ("un millon de muertos"), including the tens of thousands who succumbed to the effects of chaos and privations. The figure for war dead is now thought to be about 600,000.

N. General Franco's Government

Great Britain and France had recognized General Franco's government on Feb. 27; the United States followed suit on April 1. A victory parade in Madrid on May 19 was followed within a few days by the departure from Spain of the German and Italian combatants; and during the summer the various ministries returned to the capital. These few months saw the first stages of reconstruction, to speed which General Franco "adopted" the most severely damaged towns and granted extraordinary credits for house building, the repair of public buildings, and the rehabilitation of the transport system. The Falange, reorganized, outnumbered the Traditionalists in the government, and Ramón Serrano Súñer, appointed minister of the interior and later foreign minister,

emerged as the second strongest figure in the administration. He was brother-in-law to the *caudillo* (leader), as General Franco was now called in his capacity as head of the Falangist Party.

World War II.—With the outbreak of hostilities between Germany and the Allies in September 1939, General Franco was quick to reaffirm Spain's neutrality. Six months earlier, in March, Spain had joined the anti-Comintern bloc; but a much more significant action, as it proved, was the conclusion only four days after this of a treaty of friendship and nonaggression with Portugal. This agreement, reinforced by a protocol of July 1940, seemed calculated to rule out any step capable of involving Spain in war with Great Britain's oldest ally. The Soviet-German Pact (August 1939) came as a great shock to Spanish idealism, and the overrunning of Catholic Poland brought consternation to "the most Catholic country in Europe." Germany's attack on the U.S.S.R. in June 1941 helped to restore the perspective, and Spain dispatched its Blue Division of volunteers to fight by Germany's side in the Ukraine. In a speech of July 18, 1942, General Franco reiterated his stand: "Yesterday, today, and tomorrow, for the countries of Europe there exists only one danger—Communism." Earlier he had promised 1,000,000 volunteers for the defense of Berlin should this ever be threatened by the Russians.

Meanwhile, Spain had used the occasion of Italy's entry into the war to alter the status of Tangier, and on Nov. 24, 1940, the administration of the International Zone was formally combined with that of Spanish Morocco. England refused to recognize this unilateral action and protested against attacks on British property in Tangier; but a *modus vivendi* was reached on Feb. 26, 1941, when Great Britain, while reserving all rights, accepted the new situation meantime. The redefinition, likewise in June 1940, of Spain's own status as one of nonbelligerency and the emphasis laid on its new-found "will to empire" reflected confidence in an impending Axis victory and the desire to share in any redistribution of colonial territories. The presence of German troops at the Pyrenees after the French collapse weighed heavily thereafter on Spanish policy; but although General Franco journeyed to Hendaye, Fr., on Oct. 23, 1940, to meet Hitler and to Bordighera, It., to meet Mussolini four months later (Feb. 12, 1941), he succeeded in avoiding irrevocable commitments. The creation in November 1940 of the Council of Hispanity, its concern being "all activities tending to the unification of culture, economic interests, and power throughout the Hispanic world," was aimed at the recovery of prestige and influence in Spanish America. The atmosphere across the Atlantic, as country after country identified itself with the Allied cause, was, however, unsympathetic in the main toward Spain and its totalitarian leanings, Argentina being the notable exception.

By late 1942 the course of the war was giving General Franco cause for second thoughts. The dismissal of the violently germanophile Serrano Súñer from the foreign ministry in September was one sign that Spain was cautiously reverting from nonbelligerency to neutrality. The Allied landings in North Africa in November, followed by the German occupation of the whole of France, threatened Spain for a moment with involuntary involvement in hostilities, and partial mobilization was decreed. But the danger passed, and in December an Iberian bloc was formally cemented with Portugal. This, described by Gen. Francisco Gómez Jordana y Souza, now foreign minister (it was he who had signed the original nonaggression pact with Portugal in 1939), as "an instrument of peace capable of playing its part in international policy," confirmed the new direction; and with the collapse of Italy in July 1943 Spain began to urge the desirability of a compromise peace, in which it aspired to play the role of mediator. The Allies, however, were still not convinced that Spanish neutrality was genuine and in February 1944 the United States, to encourage its stricter observance, imposed an embargo on oil shipments to Spain. This bore fruit in an agreement of May 2, Spain giving satisfaction on various outstanding Allied grievances concerning exports of wolframite to Germany, German agents in Tangier, Italian ships in Spanish ports, and the Blue Division.

Ostracism by the United Nations.—The ending of the war in Europe in May 1945 and the political landslide to the left that swept the continent, from Great Britain to Greece, as its first consequence confronted the Spanish regime with a position of acute difficulty. Overtures from Spain for a voice in the peace settlement and urging the need for a Western entente against Soviet expansion were disregarded. The Potsdam declaration of July branded Franco's regime as unfit to associate with the United Nations, one-third of whom were Spain's daughter nations in Latin America. In August, at an international conference in Paris on Tangier, the U.S.S.R. but not Spain being represented, Spain was given a month in which to remove its troops from the city. In that same month Mexico, which had never recognized the new Spanish regime, granted hospitality and recognition to a Spanish Republican government in exile. The culmination of this general ostracism was the decision of the United Nations in December 1946, by 34 votes to 6, to demand the replacement of the regime by one "deriving its authority from the governed," coupled with the recommendation that all member nations should recall their ambassadors or ministers from Madrid. Apart from Portugal and Argentina, Spain had few friends left. This danger had already been foreseen. Once the tide of war had clearly turned, the "totalitarian state" had given way to a new term, "organic democracy." A pseudo *Cortes* had been inaugurated (March 1943), and Franco had begun to drop hints of a restoration of the monarchy. In October 1944 a first approach to elections took place, for the renewal of the syndical organization. This last was the residual sphere of influence of the Falangist Party, whose program of national syndicalism had earlier supplied the doctrinal basis for the regime. But the party's entanglement in government had come to be felt as an embarrassment. Party control of press, radio, and propaganda had been transferred in August to the ministry of education. The Falangist salute had been abolished by decree in the following September, and the title of *caudillo* was supposed to recede with the party into the background.

Relations with the Church.—The appointment as foreign minister, in the far-reaching cabinet reshuffle (July 1945), of Alberto Martín Artajo, former president of Catholic Action and not a party member, was likewise aimed at foreign opinion and particularly at closer relations with the Vatican. Repeal of the divorce law, restoration of religious education and of budget provision for the church, and the return to the Jesuits of their property and prerogatives had followed close on victory in the Civil War, but there had been no progress toward the new concordat promised in the program of the "new state." A *modus vivendi* reached in June 1941, to allow the filling of vacant sees, then numbering about 20 out of 55, merely revalidated the first four articles of the concordat of 1851. The church distrusted certain of the totalitarian implications of the regime and by 1945 was demanding (as in a pastoral letter issued on Aug. 28 by the archbishop of Toledo and primate of Spain, Enrique Pla y Deniel, to mark the end of the world war) an end to the "constituent period" and a return to a constitution "in conformity with Spain's historic tradition and the degree of political education of the Spanish people."

The new concordat between the Holy See and Spain, confirming Spanish loyalty to the Church of Rome, was signed only on Aug. 27, 1953. Concessions were made to ecclesiastical objections to some reforms in Spanish schools before the Secondary Education Act passed the *Cortes* at the end of February 1953.

Franco and the Monarchy.—As during the war, however, a restoration of the kingship was still to Franco only the last resort. In March 1945 the pretender Don Juan (1913–), conde de Barcelona, third son of Alfonso XIII (who had designated him as his successor before his death in Rome on Feb. 28, 1941), had called on Franco to resign, offering Spain a new constitution to be determined by popular vote, a legislative assembly, guarantees of political liberty and individual rights, recognition of regional characteristics and an amnesty. Only the mention of an amnesty provoked any response. On April 29 it was announced that all political charges against Republicans were being dropped and exiles were invited to return. In October came a proclamation of full pardon for all prisoners convicted of political offenses committed during the Civil War. Coming six and a half years after the end of hostilities, the detail was eloquent of the animosity with which the

regime had persecuted its political opponents. The execution on Oct. 17, 1940, of Lluis Companys, former president of Catalonia, handed over by the Vichy government, was perhaps the blackest and most impolitic stain on the record.

Political evolution did not signify any abandonment of "the fundamental principles of the state," which were declared to be sacrosanct in a charter of rights, the *Fuero de los Españoles*, submitted to the *Cortes* on July 19, 1945; and it gradually became clear that by a restoration Franco understood not a return to the traditional monarchy but only such a solution for the problem of the succession as would guarantee the continuity of those principles under a guise more acceptable to public opinion. This was made explicit in a Law of Succession published on April 1, 1947, by which Spain constituted itself a kingdom and the successor to Franco was declared to be that person of royal blood with the best right who fulfilled certain conditions, swore to observe the fundamental laws of the regime and was approved by a two-thirds vote of the *Cortes*. Failing such a king, a council of the kingdom, acting jointly with the government, would nominate a regent.

In December 1954 Franco and Don Juan agreed on the 16-year-old Infante Don Juan Carlos (1938–), eldest son of the latter, as presumptive heir to Franco (then aged 62). The step provoked renewed Falangist opposition to the idea of an eventual restoration.

In December 1966 a new Organic Law of the State was approved in a national referendum. By this law Spain was to have a prime minister, chosen by the head of the state from a list of three names proposed by the Council of the Realm. His term of office was to be five years, but he would be removable by the head of the state. The law also provided for the election to the *Cortes* of two deputies elected from each province by heads of families and their wives. The membership of the Council of the Realm was to be increased from 13 to 17, the additional 4 members being elected by the *Cortes*. The new law also proclaimed religious liberty for non-Catholics as an established legal right.

International Relations.—The exclusion of Spain from aid under the Marshall Plan (*q.v.*) and the failure of repeated approaches to the United States for loans were aggravations of the acute economic difficulties that had weighed on the regime ever since the end of the Civil War. A succession of droughts and bad harvests, together with the refusal of foreign credits, gravely impeded the nation's recovery but did not suffice seriously to threaten the regime. Apathy, born of the devastation of the Civil War and the desire at all costs to avoid another, had become a major political factor. The Army was still behind the regime, and the psychological effect of the ostracizing of Spain by the United Nations had been to bind Spaniards together in defiance of outside interference. By late 1950 the withdrawal of ambassadors was seen to have had the opposite effect to that intended, and on Nov. 4, by 38 votes to 10, with 12 abstentions, the United Nations rescinded its resolution of December 1946.

A week later Spain was admitted to full membership of FAO (to UNESCO not until November 1952, and to the United Nations on Dec. 14, 1955). Diplomatic relations were resumed with the United States (December 1950), Great Britain (January 1951), and other powers; and in July 1951 the United States initiated discussions with Spain on the latter's contribution to Western defense. These fructified in the bilateral agreements of Sept. 26, 1953, providing for the construction and joint use of naval bases at Cádiz and Cartagena and air bases near Madrid, Saragossa, and Seville; economic aid to Spain; and aid in the organization and equipping of Spain's defense forces. On its expiry in 1963, the pact was renewed for a further five years, and a four-year economic development plan for 1964–67 between Spain and the United States was signed in the same year. In April 1956 Spain concluded an agreement with Mohammed V of Morocco, by which the Spanish protectorate of Morocco, as laid down by the treaty of November 1912, was incorporated into the new independent state of Morocco, except the enclaves (plazas) of Melilla, Ceuta, Alhucemas, Chafarinas, and Peñón de Vélez. The remaining colonies of Spain now consisted of five small islands off Morocco, Ifni and Spanish Sahara in northwest Africa, and the Fernando Po Islands and Río Muni in West Africa. (W. C. An.; W. H. Ca.)

VI. POPULATION

The population of Roman Spain in the 1st century A.D. was estimated at between 6,000,000 and 7,000,000. By the end of the empire, this had risen by about a third. Modern demographic data began with the 1787 census which gave a total population for Spain and the "adjacent" islands of more than 10,000,000. By the end of the 19th century this had nearly doubled (though it was a relatively smaller increase than that for many of the newly industrialized countries of Western Europe). From 1900 to 1930 the population increased by more than 25%, and despite the ravages of the Civil War (1936–39), the rate of increase in the following decade did not decline. The 1950 census registered a population of 27,976,755 (an increase of 8.1% over 1940), and the 1960 census a total of 30,430,698 (an increase of 8.8% over 1950), with 1,061 women to 1,000 men. The death rate in 1960 was 8.8 per 1,000, compared to 28.9 in 1900, while the corresponding figures for the birth rate were 21.8 and 34.8.

The majority of the rural population is distributed around the pluviose coasts and in the valleys stretching inland from the coast, in a predominantly dispersed pattern. The remainder is concentrated in villages in the more arid central plains. Urban increased considerably after the Civil War, though the proportion of population living in towns of more than 150,000 is still lower in Spain than in most other Western European countries. In 1950 Madrid, Barcelona, Valencia, Seville, Málaga, Saragossa, Bilbao, Murcia, Las Palmas, Córdoba, La Coruña, and Granada (*qq.v.*) had populations exceeding 150,000; by the mid-1960s the number of such towns included Palma (reflecting the rapid rise of Majorca as a tourist centre) and Valladolid. (M. C. S.)

VII. ADMINISTRATION AND SOCIAL CONDITIONS

1. Constitution and Government.—The "new state" promulgated no formal constitution but five fundamental laws of the nation: the Labour Charter (March 1938), the Law of the *Cortes* (July 1942), the *Fuero de los Españoles* (a charter of rights; July 1945), the National Referendum Law (October 1945), and the Law of Succession (approved by the *Cortes* June 1947). To these was added the Organic Law of the State (November 1966; approved by national referendum, December 1966).

The Law of Succession defined Spain politically as "a Catholic social and representative state hereby constituted, in accordance with tradition, a kingdom." General Franco, head of state, would be succeeded eventually by a king, being a person of the blood royal acceptable to the Council of the Realm, the government, and the *Cortes* or, failing such, by a regent equally acceptable.

The Council of the Realm, instituted by the Law of Succession, is the supreme consultative body, advising the head of state on all matters of his exclusive competence, such as declaring war or making peace, and the choice of a successor. Seven of its 17 members are ex officio, 7 elected by the *Cortes*, and 3 nominated by the head of state. The *Cortes*, established by a law of July 1942 as the "'superior organism for the participation of the Spanish people in the work of the state," discusses and may propose laws; the head of the state, who with his ministers normally initiates legislation, has the power of veto. By the Organic Law of the State, 100 of the *Cortes'* members, previously either directly appointed by the head of state or elected by official organizations such as the syndicates, municipalities, and professional bodies, are elected by heads of families and their wives, two members being elected to represent each province. Elected members of the *Cortes* serve for three years. The *Cortes* functions both as a whole, to consider all major legislation, and by commissions. It has no control over the government, though members may ask questions of ministers. Laws of outstanding importance are submitted further to national referendum. The head of the state presides over the cabinet, on which the secretary general of the Falangist party sits without portfolio. The Organic Law of the State provided for the division of executive powers between the head of state and a prime minister. The former selects the latter from a list of three names submitted by the Council of the Realm. The prime minister serves for five years but can be removed by the head of state although not by the *Cortes*.

Since April 1937 there has been only one legally constituted political organization, the Falange Española Tradicionalista y de las Juntas de Ofensiva Nacional Sindicalista, with the *caudillo* as president of the Junta Política. This single party (commonly called the Falange) is controlled by a National Council of about 100 members.

Local Government.—The 50 provinces (except for Navarra, the three Basque provinces, and the Balearic Islands) are named after their capitals; they are intermediary administrative units between state and municipality (*see* Table). The provincial councils

*The North African plazas are not included. †1 sq.mi. = 2.59 sq.km.

(*diputaciones provinciales*) are elected partly from representatives of municipalities, and partly from economic, cultural, and professional bodies. Half of the members change every three years. Civil governors are appointed by the government and are responsible for provincial administration to the Minister for the Interior. The *mancomunidad*, or interprovincial association for the integration of common interests, continues in the Canary Islands (two provinces since 1927). A municipal law of 1945 renewed the bases of local administration.

In towns of more than 10,000 inhabitants, the mayor (*alcalde*) is appointed by the government. In smaller communities, he is selected by the civil governor of the province. One-third of the town councilors (*regidores*) are elected from representatives of heads of families; two-thirds in equal numbers from those of syndical organizations, and of economic, cultural, and professional bodies. The council (*ayuntamiento*) is mainly advisory in function since the mayor is regarded as a delegate of the central government. All Spaniards over 21 years of age have an electoral vote.

2. Welfare Services and Living Conditions.—The Labour Charter (1938) provided for a better distribution and remuneration of the working classes. Under the Law of Family Subsidy (1939) all working people are compelled to contribute 1% of their earnings (6% being added by employers) in a system of social insurance which entitles all families with 2 to 12 children under 14 years of age to a proportional monthly allowance, with an extra allowance to families over 12. A bonus is also given on marriage and motherhood. Since 1942 health insurance has been obligatory; various occupational insurance plans have been started, and since 1949 there have been old age and disablement pensions.

After the Civil War, a commission for devastated regions was set up and many new villages were planned and constructed. A National Housing Institute was founded which since 1957 has been a ministry. By the mid-1960s more than 250,000 dwellings were being completed annually.

Despite the economic improvement of the nation as a whole, many Spaniards in the mid-1960s were living just above the poverty line. Average annual income was below $400 (£142). However, through collective bargaining, wages were on the rise and demands far exceeded the minimum daily rate of 60 pesetas ($1.05 or 7*s.* 6*d.*) which was decreed in 1963. This in turn has released a rise in prices, particularly in foodstuffs, and the cost of living was soaring faster than anywhere else in Western Europe.

The income tax structure is based mainly on the narrow (rich) section of the population where evasion is comparatively easy.

3. Justice.—"Pending the definitive organization of the administration of justice in the New State," the Supreme Court (*Tribunal Supremo*) was reconstituted in 1938. The president and 15 of its 20 members are direct government appointees and 5 are indirect. There are 15 Territorial High Courts (*Audiencias Territoriales*), and each province has its own court of first instance (*Audiencia Provincial*) for criminal offenses. Below these are more than 550 district courts which hear civil cases in the first instance, and more than 9,000 municipal and related courts which deal with petty offenses and minor civil issues. The jury system exists except for military trials. Spanish law is founded on Roman law, Gothic common law, and surviving elements of medieval customary and local law. (M. C. S.)

Police.—The maintenance of public order is the responsibility of the Ministerio de la Gobernación (Ministry of Home Affairs) which exercises executive power through the police, both armed and unarmed, and the Guardia Civil. The police forces operate in the more important urban areas, while the Guardia Civil is confined to rural sections of the country.

4. Education.—The country is divided into 12 educational districts, and each has a university as a centre. In the mid-1960s there were more than 100,000 primary schools with about 4,000,000 pupils, and more than 2,600 secondary, technical, and vocational schools with 1,070,000. Primary education is free and compulsory, in theory, up to the age of 14.

All instruction is given in Castilian. Boys and girls are usually segregated except in small schools in rural areas. Secondary education caters to students between 10 and 17 years of age. The course (*bachillerato*) is divided into two parts: the elementary, lasting four years; and the advanced, lasting two years. At the end of the advanced stage, state examinations (prerequisite to university entrance) are conducted by the universities. Choice of textbooks in secondary schools as in primary schools is limited, being subject to official approval. Sexes are again segregated. Both state institutions and private ones (run mainly by religious orders) exist.

There are 12 state universities: at Salamanca (founded in 1218); Valladolid (1346); Barcelona (1450); Valencia (1500); Santiago de Compostela (1501); Seville (1502); Madrid (1508); Granada (1526); Saragossa (1542); Oviedo (1608); La Laguña in the Canary Islands (1701); and Murcia (1915). The Pontifical University of Commillas was founded by Pope Leo XIII in 1892 and the Ecclesiastical University of Salamanca dates from the 12th century. There are seven basic faculties in state universities: philosophy and letters; science; law; medicine; pharmacy; veterinary science; and political, economic, and commercial science. Some of the universities do not have all of these, while Cádiz has a medical and science faculty affiliated with the University of Seville. The teaching syllabus comprises two stages: graduation and doctorate, but Madrid alone can confer the doctorate. The halls of residence (*colegios mayores*) retain a medieval tradition but have also developed a modern character. At first they were centres of further studies, but are now mainly for undergraduates. Under the Law of University Ordination (1943) religious instruction is compulsory; there is no university autonomy and teaching staff are state-appointed. However, by the mid-1960s students, notably in Madrid and Barcelona, were actively opposing the Sindicato Español Universitario (the government-controlled organization to which they were all compelled to belong) and were agitating for academic freedom and for a new university order.

By law each factory is required to maintain a technical school or to send apprentices to one. Pupils attend these directly after primary school. In 1957 the Technical Teaching Law marked the beginning of the union of technical institutes with the universities, and by the 1960s there were four technical universities and more than 90 technological colleges and institutes in Spain.

Seminars take place in Santander, Seville, and Barcelona universities. There are also many courses for foreigners, especially organized in summer schools. Outside Spain there are important Spanish colleges and institutes. Other educational centres include primary teacher training colleges, naval and military schools, and schools of art, architecture, and music. Apart from research carried out in the universities and technical institutes, a Higher Council for Scientific Research was started in 1949, and an Atomic Energy Board was founded in 1951.

5. Defense.—The standing army consists of eight corps of two divisions each, corresponding to the eight military regions of Madrid, Seville, Valencia, Barcelona, Saragossa, Burgos, Valladolid, and La Coruña. A ninth military region (Granada) was constituted in 1944, with one division. There are two general commands in the Balearic and Canary islands, and an independent cavalry division and a general artillery reserve. Some military units are stationed overseas, mainly in the places of Spanish sovereignty in Morocco (Ceuta and Melilla) as well as at Villa Cisneros, in Spanish Sahara. The Navy is rather poorly equipped by Western European standards; the main naval docks are at El Ferrol del Caudillo, Cartagena, and Cádiz. The Air Force was created in 1939, and Spain is divided into five air regions, with two more in the Balearics and the Canaries.

On Sept. 26, 1953, the United States and Spain signed three 10-year agreements covering the construction and use of military facilities in Spain by the U.S. in return for military and economic aid to Spain. These agreements were renewed in 1963 for a further five years. (M. C. S.)

VIII. THE ECONOMY

The Spanish economy suffered three severe economic shocks caused by the general world depression in the early 1930s, the Civil War of 1936–39, and World War II which was followed by a United Nations "boycott" (1946–50). Agricultural production did not regain its 1929 level until 1951, by which time industrial production was only about one-third above the 1929 level. A remarkable economic upsurge began after 1953 when the United States supplied aid for the improvement of communications and the building of major dams for irrigation and hydroelectric power. This was quickly followed by U.S. private investment and in the 1960s by a flood of foreign capital; the financial position of the country vastly improved, supplemented by the booming tourist trade which brought in higher receipts than ever before. But rapid economic expansion was accompanied by a rising cost of living, the threat of inflation, and labour unrest. The utilization of labour in agriculture remained a problem, especially in the typically feudal regions of Andalusia and Extremadura.

A. Production

1. Agriculture.—In the mid-1960s about 40% of the nation's labour force scraped a bare living from the land, contributing little more than 25% to the gross national product which amounted to less than $280 (£100) a head. Agricultural methods lacked mechanization and were often primitive. Much potential farm labour was wasted in seasonal unemployment and there were about 2,000,000 redundant workers. By the 1960s there was a migratory trend of rural labour toward industry, both inside Spain and abroad. The areas under wheat, vines, and olives are proportionately extensive but soil erosion is widespread because of many years of overtilling and overgrazing. In addition, much of the cropped area is dependent upon the vagaries of an uncertain rainfall whose variability has at times greatly affected the national income, for wheat is the chief crop in 27 provinces and olives in 5. Frost is frequently a formidable threat to the Valencian orange crop.

The problem of the latifundia, large landed estates where the rural population can find employment only during the crop seasons, is a continuing one. In 1930 there were about 7,000 proprietors (mostly absentees) who owned about 14,826,800 ac. (6,000,000 ha.) in Extremadura, Andalusia, and La Mancha. In 1939 the National Institute of Land Settlement was established, but by 1956 only 494,230 ac. (200,000 ha.) had been divided. After that a new policy was adopted, involving the concentration of small holdings into larger units, and by the mid-1960s more than 1,500,000 ac. (607,000 ha.) had been redistributed with 4,500,000 ac. (1,821,000 ha.) under negotiation. The supply of fertilizers, formerly an acute problem, has greatly improved and wheat yields have increased. But there is evidence of inefficient marketing of farm products, including lack of storage facilities.

Crops.—Wheat is the most important cereal, accounting for about one-quarter of the value of all agricultural produce. It is grown chiefly in the districts of Tierra de Campos, Tierra del Pan, Coca, Cuéllar, and Medina del Campo (all in Old Castile); Saragossa (in Aragon), La Sagra and La Mancha (in New Castile); and La Serena and Tierra de Barros (in Extremadura). Barley, formerly more widespread, is still the important grain of the southeast; it is now chiefly a fodder crop. The cereal lands are still farmed according to traditional practices, especially the biennial rotation of crops (*año y vez*). Only one-eighth of the cultivated land is cropped continuously with legumes or sugar beet. Pulses are a staple crop of the Meseta. Rice is grown in Valencia and the Ebro Delta and some is exported to the Federal Republic of Germany. Potatoes (an important crop in Galicia), beans, and onions are also significant.

The olive dominates in Andalusia, as does wheat in the Castiles. It covers nearly half the cultivated lands of Jaén, one-third of those of Córdoba, and one-quarter of those of Seville. Almost the whole olive crop is utilized for the production of oil, but yields are quite variable. The vine is especially important in La Mancha, in La Rioja, and in the hills of Catalonia, Valencia, and Málaga. As third largest world producer, Spain suffers from over-production of inferior wines, because imports into France have declined and Spaniards drink less than formerly. But brandy and sherry from Cádiz and Jerez de la Frontera, and dessert wines from Valencia and Málaga find a steady demand. Fruit trees are widespread but production tends to be specialized in certain areas: apples and pears in the north and northwest; figs and almonds in Majorca (Mallorca) and Alicante; peaches and apricots in Murcia; and citrus fruits especially in Valencia and Castellón de la Plana. Esparto or alfa grass covers a large area in the southeast. Hemp and cotton are produced in appreciable quantities. Tobacco is grown on the southeast coast, but sugar beet is much more important.

Irrigation.—With periodic drought affecting about 40% of all

(LEFT) KIT ROBBINS—RAPHO GUILLUMETTE; (ABOVE) STIG T. KARLSSON FROM BLACK STAR

THE FISHING AND WINE INDUSTRIES ARE IMPORTANT

(Left) A wine taster in southwestern Spain; (right) fishermen hauling in tunny in Galicia Province

Spanish land, irrigation has become a necessity. The first large canals and dams were built at the end of the 18th century, such as the Canal Imperial de Aragón on the Ebro and the Pantano de Puentes near Lorca. The first national project dates from 1898, and was followed by those of Pantano de Gassel (1911), the Río Guadalhorce (1926), Pardo (1933), and Río Peña (1939). It is estimated that nearly one-third of the total river flow is controlled by about 140 major reservoirs. A system of more than 200 mi. (320 km.) of modern trunk canals irrigates about 1,200,000 ac. (485,600 ha.), and older canal systems a further 750,000 ac. (303,500 ha.). An area as large again is irrigated by other methods. In the late 1950s the rate of development was accelerated, water storage capacity being increased by about two-thirds; and by the mid-1960s (under the 1964–67 development plan) more than 30 dams were planned or under construction, involving irrigation improvement of almost 6,000,000 ac. (2,428,000 ha.) and the supply of hydroelectric power (see *Economic Planning*, below).

Livestock.—Pastoralism has been fundamental in the history of Spain and is still important. More than half of the cattle in Spain are concentrated in the humid north, especially dairy cows in the Cordillera Cantábrica. Sheep are characteristic of the Meseta, with three basic breeds: the long-wooled churro, the short-wooled merino, and the manchegan. Transhumance is still practised from the mountains of León and Old Castile to Extremadura. Goats are best suited to the arid conditions of the southeast, and pig rearing is common in the holm oak woodlands of Extremadura.

2. Fisheries.—Despite the lengthy Spanish coast line, there are few natural harbours except in Galicia, which has the richest fishing grounds and where Vigo is the main fishing port. About three-quarters of the total annual catch (averaging more than 1,000,000 metric tons) normally comes into the ports along the northern and western Atlantic coasts. The chief fish landed are sardines, anchovies, hake, cod, tunny, bream, mollusks, and crustaceans. About 800 fish-packing plants preserve sardines and tunny.

3. Forestry.—To counteract erosion, between 1939 and the early 1960s more than 3,700,000 ac. (1,500,000 ha.) were reafforested. The total area of forest and potential forest was estimated at 58,000,000 ac. (23,471,000 ha.), more than half of which was practically denuded of trees. The commonest trees are the evergreen oak, the maritime pine, and the Aleppo pine, and there is much cork oak, mainly in Andalusia and Catalonia. (*See* also *Vegetation*, above.)

4. Mining and Minerals.—Until the early 1930s more than half the mining investments were in foreign hands and mining was geared to the needs of Western European markets. By the mid-1960s the mining industry was undergoing radical reorganization. Marginal workings were closed and the number of miners diminished, while investment in pits offering the greatest economic potential was increased. The rich veins of hematite (rubio iron ore) of Bilbao, which once accounted for two-thirds of the national output, now represent less than 3% of the national reserves. In the mid-1960s Spain produced 3,000,000–4,000,000 metric tons of crude steel and about the same quantity of pig iron annually, at costs above those of other Western European countries. Production was more than double that of the mid-1950s, largely because of the opening (1957–58) of ENSIDESA (Empresa Nacional Siderurgica, SA) open-hearth steel mills at Avilés by the Instituto Nacional de Industria, established by the government in 1941.

Coal produced, chiefly from Asturias but also from the lower hills of Sierra Morena, is inadequate (about 14,000,000 metric tons annually in the mid-1960s) and of inferior quality, and considerable quantities of coking coal have to be imported.

Spain, however, is rich in other minerals, most of which are exported: mercury (from the ancient mines of Almadén in Ciudad Real), wolframite, tin, zinc, lead, and manganese. The development of electricity production has stimulated the expansion of electrometallurgical industries; these produce electrolytic copper, aluminum at Alicante and Sabiñánigo, and ferrotungsten and ferromanganese in the Basque provinces.

Oil refining is a relatively new development. Until 1949 there was only one refinery at Tenerife (1930); since then the plant at Escombreras, near Cartagena, has nearly trebled its refining capacity and that at La Coruña can deal with 2,000,000 bbl. of crude oil a year. A hydrogenation plant at Puertollano in Ciudad Real, to produce lubricants from shale oil, was also opened in the 1950s.

5. Power.—Power shortages have seriously handicapped industrial production, especially during seasons of drought. Most of the registered output (more than 24,300,000,000 kw-hr. in the mid-1960s) was provided by hydroelectric stations of which there were more than 1,000. About one-fifth of the water power potential was being utilized, although the proportion varied considerably from region to region. One of the most ambitious schemes was the chain of hydraulic plants on the Miño-Sil river system. In the mid-1960s major dams were being built on the Duero (Douro) at the Portuguese frontier and in the Aragonese Pyrenees. An atomic pile was constructed in Madrid and an atomic power station at Sobrón on the upper Ebro was planned.

6. Manufacturing Industries.—Despite significant changes in the growth of manufacturing in the 20th century, the location of industry is still strongly marked by historical inertia. Bilbao has been a steel centre since the Middle Ages; Éibar in Guipúzcoa has been noted for its production of armaments since the 14th century; the ceramic wares of Manises in Valencia Province, and the paper manufacture of Játiva go back to Moorish times; and Béjar, Segovia, Soria, and Burgos have long been woolen centres. Another feature is the marked concentration of the chief industries in a few districts, namely Barcelona, the province of Valencia, the north coast, and Madrid, in that order of importance. The Barcelona region has about one-quarter of all the national enterprises, with three-quarters of the cotton spindles and looms, and one-third of the entire manufacturing labour force; in addition to textiles, chemicals and engineering are also important. There are considerable manufactures at Valencia and its neighbouring towns, and at Murcia, Alicante, and Palma; apart from food processing, liqueurs, and wines, there are textiles, timber, footwear, light engineering, and chemical industries. The northern heavy industrial centres include the coal-mining towns of Oviedo and the metallurgical centres of Santander and the Basque provinces, of which Guipúzcoa and Vizcaya provinces also have en-

gineering, paper, chemicals, and ancillary industries. By the 1960s Madrid had rapidly developed a wide range of industries, notably food and drink, textiles, and engineering, the latter including the Pegaso motor vehicle factory and the Hispano aircraft works. Out of nearly 250 towns with more than 10,000 inhabitants each, only about 45 may be classified as manufacturing centres while a further 30 are largely concerned with food and drink processing.

7. Economic Planning.—In the backward areas of Spain problems of transport and unemployment have high priorities. Previously, many of the national projects for the extension of electric power, irrigation, communications, and particularly industries, were treated in isolation, but in 1952 the government began to set up regional development plans. Thus under the Badajoz plan the Río Guadiana was harnessed to produce by the mid-1960s about 250,000,000 kw-hr. annually, to irrigate 105,000 ha., to facilitate the settlement of 10,000 colonists, and to employ permanently nearly 60,000 agricultural workers. The pivot of the plan was the construction of the Cijara and Orellán dams. Similarly, in the Jaén plan ten dams on the upper Guadalquivir, Guadiana Menor, and their tributaries were to be built, perennial irrigation was to be extended, and new settlements and industries established. In 1954 a similar 14-year plan for the right bank of the Ebro was launched, designed to benefit the steppe lands of Cinca, Las Bárdenas, and Monegro. Plans on similar lines were announced for Cáceres, Ciudad Real, Almería, and Galicia. By the 1960s the first plants of the Miño-Sil hydropower projects had begun to function.

In 1959, because autarky often proved unworkable, Spain asked the World Bank for advice on economic reforms. The conspicuous result was a four-year development plan (1964–67) which envisaged a total investment of 334,997,000,000 pesetas (more than $5,500,000,000) in both the public and private sectors, with transport, housing, irrigation, and education taking precedence. The plan coincided with the improvements due to foreign investment; its goal was an annual 6% increase in the gross national product.

B. Trade and Finance

1. Foreign Trade.—Food commodities (notably olives and olive oil, oranges, fruits, and vegetables) average more than half of the total value of exports, while manufactures and raw material (chiefly iron ore and pyrites) represent each from one-fifth to one-quarter. Most of the imports consist of raw materials (mainly cotton, petroleum and products, and fertilizers) and manufactured goods, the remainder being foodstuffs. By the mid-1960s more than one-third of both imports and exports came from the European Economic Community; the European Free Trade Association (especially the United Kingdom) and the United States were the other chief sources of reciprocal trade. A secondary trade was maintained with Latin America. After restrictions on foreign trade were lifted in 1959 most imports entered the country freely.

With government sponsorship, the tourist trade increased at a rapid rate in the 1950s, and by the mid-1960s, together with emigrants' remittances, brought to Spain foreign exchange almost equal to the total value of all visible exports. The number of foreign tourists (excluding day-trippers) exceeded 14,000,000 annually. This source of foreign capital inflow helped to fill a chronic trade gap caused by expanding imports (mainly machinery).

2. Currency, Banking, and Finance.—The unit of currency is the peseta, divided into 100 céntimos. In 1959 the peseta was stabilized at a devalued rate (U.S. $1 = 60 pesetas; £1 = 167–168 pesetas), and by the mid-1960s it had become one of the stronger European currencies.

The central bank is the Banco de España, in whose profits the government has participated since 1922. The commercial banks are regulated by ordinance and have a strongly entrenched control over industry. Largely because the public prefers to keep its savings on deposit rather than invest in securities, the banks control more than half of the issued capital of the Spanish limited-liability companies; thus seven leading banks control about two-thirds of industry. After 1941 all foreign banks were voluntarily nationalized.

By the mid-1960s government annual revenue and expenditure both averaged more than 120,000,000,000 pesetas. About one-quarter of the revenue came from direct taxation and more than one-half from indirect, with a small proportion from state monopolies and properties. Chief expenditures were on defense, public works (particularly dams), and the servicing of the public debt.

C. Transport and Communications

1. Roads.—Most of the large centres were originally sited on the well-developed Roman road system. But this was allowed to fall into decay, and only in the 18th century were the royal routes improved. There was little development or repair after the Peninsular War, and not until the 1920s was much done. The greatest improvements were made after the start of U.S. aid in 1953. The Madrid-Cádiz highway is now in excellent condition, and there have been considerable improvements on the Madrid-Irún and Madrid-Saragossa roads. By the mid-1960s the total length of the roads exceeded 83,000 mi. (134,000 km.) but only about three-fifths were macadamized. However, prospects for improvement are good, for vehicles are heavily taxed and tourists also pay a tax destined for the development of communications. Regular motor coach and bus services carry more passengers annually than the railways.

2. Railways.—The first railway (Madrid-Aranjuez) was opened in 1848, and the active period of trunk-line construction was between 1855 and 1900. Of the total length (11,226 mi.; 18,066 km.) one-quarter is narrow-gauge, only one-seventh has double track, and one-sixth is electrified. In 1941 the broad-gauge lines were nationalized and taken over by the organization known as RENFE (Red Nacional de los Ferrocarriles Españoles). After World War II traffic greatly increased, trains were faster, and delays were less common. However, Spain is one of the few European countries that remains deficient in rail transport and there is an urgent need for the railways that were planned long ago but not built: Madrid-Galicia, Madrid-Burgos-Santander, Asturias-Galicia, Vitoria-Bilbao, Zafra-Portugal, Jerez de la Frontera-Almadén, and especially Baeza-Albacete-Utiel-Teruel-Caspe-Lérida linked to a Lérida or Saragossa line to Luchon, France. In 1964 the World Bank loaned $65,000,000 to RENFE to finance the first stage of a 10-year railway modernization program.

3. Shipping.—As river and canal transport virtually do not exist, except for a short stretch on the Guadalquivir to Seville, coastwise traffic is important. It amounts to nearly twice the tonnage of the oversea shipping services. During and after World War II the Spanish fleet increased, but only about one-third of the merchandise entering and leaving Spanish ports is carried by Spanish shipping. The Empresa Nacional "Elcano" de la Marina Mercante, a state-organization, operates about 10% of a national gross tonnage which totaled about 2,000,000 in the early 1960s.

4. Air Transport.—The principal Spanish airlines, Iberia and Aviaco, have considerable traffic, especially on the internal routes. Iberia has regular services to North Africa, the Balearic and Canary Islands, Europe, South America, and North America.

5. Telecommunications.—The Compañía Nacional de Telegrafía sin Hilos holds a government concession for a public telegraph service with shipping. Transradio Española, SA operates radio-telegraph circuits; Bilbao is linked with the United Kingdom by cable, and Barcelona is linked with Marseilles, France. Radio broadcasting and television services (both government and commercial) are controlled by an agency of the Ministry of Information and Tourism and relay the official nation-wide news services.

SPALATIN, GEORG (1484–1545), German humanist and friend of Martin Luther to whose diplomatic influence may be largely attributed much of the early progress of the Reformation in Germany, was born Georg Burkhardt on Jan. 17, 1484, at Spalt (whence he assumed the name Spalatinus), near Nürnberg. He studied at the University of Erfurt, where he took his bachelor's degree in 1499. There Nikolaus Marschalk, the most influential professor, made Spalatin his amanuensis and took him to the new University of Wittenberg in 1502. In 1505 Spalatin returned to Erfurt to study jurisprudence and joined a group of humanists led by Mutianus Rufus. He became a teacher at the Georgenthal monastery, was ordained priest in 1508, and in the same year became tutor to the heir of Frederick III the Wise, elector of Saxony. In 1511 he was given a canon's stall at Altenburg and made preceptor to the elector's nephews, Otto and Ernst of Brunswick-Lüneburg, who were studying at Wittenberg University, where Spalatin met Luther. But the elector valued his advice so highly that in 1516 he summoned Spalatin back to the court to be librarian and chaplain.

Spalatin managed all the elector's correspondence, and it was he who in 1518 persuaded Frederick to give Luther his protection during the indulgence controversy. He also won for Luther a more favourable reception at the Diet of Worms (1521) than the emperor Charles V was at first prepared to give. It is not certain whether Spalatin fully appreciated the difference between humanism and Lutheranism. He several times tried to dissuade Luther from publishing his opinions, but he nonetheless translated Luther's Latin writings for the elector, as well as those of Philipp Melanchthon and Erasmus.

Spalatin was also the valued adviser of the two succeeding electors of Saxony, John and John Frederick. He became superintendent of the church in Saxony, where he organized the Reformation. From 1530 he worked with Melanchthon on the preparation of the Augsburg Confession, and he took part in the formation of the Schmalkaldic League. He died at Altenburg on Jan. 16, 1545.

Spalatin's writings include *Annales reformationis*, edited by E. S. Cyprian (1718), and "A Life of Frederick III" published in *Georg Spalatins Historischer Nachlass und Briefe*, edited by C. G. Neudecker and L. Preller (1851).

See I. Höss, *Georg Spalatin* (1956); H. Volz, "Bibliographie der im 16. Jahrhundert erschienenen Schriften Georg Spalatins," *Zeitschrift für Bibliothekswesen* (1958).

SPALDING, ALBERT (1888–1953), U.S. violinist and composer of international repute, was born at Chicago, Ill., on Aug. 15, 1888, the son of a well-to-do manufacturer of sporting goods. At age seven he commenced his musical studies under Ulpiano Chiti in Florence, continuing them with Juan Buitrago in New York City and Narcisse Lefort in Paris. Spalding's debut was made in 1905 in Paris, where he appeared with Adelina Patti

a year later. His first American appearance was with the New York Symphony Orchestra in 1908, and he toured with that orchestra in Europe, as violin soloist, in 1920. During World War I he served with the U.S. air service in Italy. He played at La Scala, Milan, in 1919, and in 1922 became the first American violinist to play regularly at concerts of the Société des Concerts du Conservatoire, Paris.

His compositions include many works for the violin, as well as a suite for orchestra, a string quartet (in E minor), and works for violin and piano. He wrote an autobiography, *Rise to Follow* (1943), and a novel, *A Fiddle, a Sword and a Lady* (1953). He retired in 1950 and died May 26, 1953 in New York City.

SPALDING, a market town and urban district in the Parts of Holland, Lincolnshire, Eng. Pop. (1961) 14,824. Area, 12.2 sq.mi. It is the centre of an extremely fertile fenland area, visited in spring for its flowering bulb fields; it cans locally grown fruit and vegetables and has a large beet-sugar factory and a livestock market. The Welland River passes through the town by a deep channel. The parish church (once the priory church) of SS. Mary and Nicholas dates from 1284. Ayscoughfee Hall (15th century, now belonging to the town) was the house of Maurice Johnson, a founder of the Spalding Gentlemen's Society (1710), probably the earliest antiquarian society in England; its museum includes birds and antiquities.

SPALLANZANI, LAZZARO (1729–1799), Italian priest and biologist, a skilled experimenter in physiology, was born at Scandiano in the province of Modena on Jan. 12, 1729. At the age of 15 he was sent to the Jesuit college at Reggio di Modena, and soon went to study law at the University of Bologna, where his kinswoman, Laura Bassi, was professor of physics; she, it is said, first interested him in science. After taking orders, he was professor at Reggio, Modena (1756), and later at Pavia, where he enriched the museum by his collections from journeys along the shores of the Mediterranean. In 1785 he visited Turkey, where he made many observations. He visited Vesuvius and Sicily in 1788 and embodied his researches in *Viaggi alle due Sicilie* (1792–97).

Spallanzani studied the circulation of the blood, respiration, gastric digestion, the senses of bats, the electricity of the torpedo, the breeding of eels, and the regeneration of different appendages of Amphibia, examining the muscles, nerves, and bones with a microscope. By filtering semen he proved that spermatozoa were necessary for fertilization in different animals, and succeeded in artificially inseminating a bitch. In a controversy with J. T. Needham, he disproved (1765) the spontaneous generation of Infusoria and other microscopic organisms, which did not develop in vegetable infusions that had been boiled long enough and kept in properly closed vessels. Some of his experiments on spontaneous generation were similar to those later performed by Pasteur.

Spallanzani's great works are the *Prodromo di un'opera da imprimersi sopra le reproduzioni animali* (1768) and *Dissertazioni di fisica animale e vegetabile*, 2 vol. (1780). He died at Pavia on Feb. 11, 1799. (A. C. Cr.)

SPANDAU, a district of West Berlin in the *Land* (state) of B[illegible], Federal Republic of Germany. Pop. [illegible]. The citadel (1560–94) is the oldest well-preserved Italian-style fortification of Renaissance time in north Germany. St. Nicholas' Church (mid-14th century) is the oldest Gothic church in Berlin. Since 1946 the prison on the Wilhelmstrasse has housed the war criminals condemned by the Allies. Spandau is now the chief industrial district of Berlin, with the electrotechnical firm of Siemens in the suburb of Siemensstadt, but its parks and forests make it a weekend resort for West Berliners. Civic rights were granted in 1232; it was incorporated into Berlin in 1920. (Gü. B.)

SPANGENBERG, AUGUST GOTTLIEB (1704–1792), German bishop of the *Unitas Fratrum* (*see* MORAVIAN CHURCH), successor to Count Nikolaus Zinzendorf (*q.v.*), and founder of the Moravian Church in North America, was born on July 15, 1704, at Klettenberg in the southern Harz Mountains. He studied law at Jena but changed to theology after his conversion to Pietism in 1722. In 1728, during a visit by Zinzendorf to Jena, Spangenberg was drawn into his circle, and in 1730 he visited the Moravian community at Herrnhut, on Zinzendorf's estate of Berthelsdorf. In 1732 he was appointed to the theological faculty at Halle, but differences with the Halle Pietists, chiefly over his connection with Zinzendorf, led to his expulsion in April 1733.

Spangenberg then went to work as Zinzendorf's assistant and until 1762 devoted himself to superintending and organizing Moravian mission work. In Pennsylvania (1736–39) he founded the North American branch of the *Unitas Fratrum*. In 1741–42 he was in England organizing a branch of the movement, and received licence to preach. In 1744 Spangenberg was made a bishop of the Moravian Church and returned to supervise work in North America, where he made perhaps his most important contribution to the movement's development. After an interval in Europe again (1749–51) he extended the mission work to North Carolina. John Wesley in his *Journal* mentions several conversations with Spangenberg, which left a profound impression on Wesley and throw an interesting light on Spangenberg's theological thought.

In 1762 Spangenberg finally returned to Germany to become a member of the governing body founded to direct the Brethren after Zinzendorf's death (1760). In 1777 he was commissioned to draw up the *Idea fidei fratrum* which became the accepted statement of the Moravian belief. As compared with Zinzendorf's own writings this book exhibits the finer balance and greater moderation of Spangenberg's nature. It was chiefly through his efforts that the movement was prevented from splitting over internal differences and that it maintained its good relationship with the main body of the Lutheran Church. In his last years Spangenberg devoted special attention to education, a field in which the Brethren made valuable contributions. He died at Berthelsdorf on Sept. 18, 1792.

In addition to the *Idea fidei fratrum*, Spangenberg wrote, besides other apologetic works, a life of Zinzendorf (1772–75) and several hymns which found their way into the hymn books of many other denominations.

See G. Reichel, *August Gottlieb Spangenberg, Bishop der Brüderkirche* (1906); T. Bechler, *A. G. Spangenberg und die Mission* (1933).

SPANISH AMERICAN LITERATURE: *see* IBERO-AMERICAN LITERATURE.

SPANISH-AMERICAN WAR, a brief and decisive conflict between the United States and Spain in the year 1898. It is often cited as marking the emergence of the United States as a world power.

Origin.—The war originated in the Cuban struggle for independence from Spain, which began in February 1895. (*See* CUBA: *History*.) The destructive Cuban conflict was injurious to U.S. investments in the island, which were estimated at $50,000,000, and almost ended U.S. trade with Cuban ports, normally valued at $100,000,000 annually. On the insurgent side the war was waged largely against property and led to the destruction of sugarcane, sugar mills, and other forms of property. Of more importance than its effect on U.S. property interests was the appeal to American humanitarian sentiment. Under the Spanish commander, Capt. Gen. Valeriano Weyler y Nicolau (nicknamed the "Butcher"), supposedly loyal Cubans were herded into so-called reconcentration areas in and around the larger cities; those who remained at large were treated as enemies. In the reconcentration areas the Spanish authorities made no adequate provision for shelter, food, sanitation, or medical care for the *reconcentrados*, thousands of whom died from exposure, hunger, and disease. These conditions were graphically portrayed for the U.S. public by the sensational newspapers, notably Joseph Pulitzer's *New York World* and William Randolph Hearst's recently founded *New York Journal*. Humanitarian concern for the suffering Cubans was added to the traditional American sympathy for a colonial people struggling for independence. While these aspects of the war created a widespread popular demand for action to halt it, the U.S. was continually inconvenienced by the necessity of patrolling the coastal waters to prevent gunrunning to the

insurgents, and by demands for aid from Cubans who had acquired U.S. citizenship and then had been arrested by the Spanish authorities for participating in the rebellion.

The popular demand for intervention to stop the war and assure Cuban independence gained support in Congress. In the spring of 1896 both the Senate and the House of Representatives declared by concurrent resolution that belligerent rights should be accorded the insurgents. This expression of congressional opinion was ignored by Pres. Grover Cleveland, who firmly opposed intervention, as did his successor, William McKinley, during his first year in office. In the fall of 1897, indeed, prospects for a peaceful settlement in Cuba brightened. In Spain the Sagasta ministry, taking office upon the assassination of Prime Minister Cánovas del Castillo, announced a new policy for Cuba: Captain General Weyler was to be recalled; his reconcentration camps were to be abandoned; and a considerable degree of autonomy was to be granted the Cubans.

These concessions came too late. The insurgent leaders would now settle for nothing short of complete independence. The war went on in Cuba, and a series of incidents brought the United States to the brink of intervention. Riots in Havana in December led to the sending of the battleship "Maine" to that port, as a precaution for the safety of U.S. citizens and property. On Feb. 9, 1898, the *New York Journal* printed a private letter from the Spanish minister in Washington, Dupuy de Lôme (filched from his correspondent in Cuba), describing President McKinley as "weak and a popularity-hunter." De Lôme immediately resigned and the Spanish government tendered an apology. The sensation caused by this incident paled beside that of six days later. On the night of Feb. 15 a mighty explosion sank the "Maine" at her Havana anchorage, carrying more than 260 seamen to their deaths. Responsibility for the disaster was never determined. A U.S. naval board found convincing evidence that an initial explosion outside the hull (presumably from a mine or torpedo) had in turn touched off the battleship's forward magazine. The Spanish government offered to submit the question of its responsibility to arbitration, but the American public, prompted by the *New York Journal* and other sensational papers, held Spain unquestionably responsible. "Remember the 'Maine,' to hell with Spain!" became a popular watchword.

President McKinley, still desirous of peace, now found himself under intense pressure for intervention; the pressure came from members of his own party, the Republican majority in Congress, as well as from the Democratic minority. U.S. business interests, in general, opposed intervention and war. But such opposition diminished after a speech in the Senate, March 17, by Sen. Redfield Proctor of Vermont, who had just returned from a tour of Cuba. In matter-of-fact and unsensational language, Proctor described his observations in the war-torn island, the suffering and death in the reconcentration areas, the devastation elsewhere, the evident inability of the Spanish to crush the rebellion. His speech, as the *Wall Street Journal* remarked on March 19, "converted a great many people in Wall Street."

Yielding to the pressure, the president on March 27, 1898, sent what amounted to an ultimatum to Madrid. Let Spain, he asked, abandon reconcentration, declare an armistice, and accept U.S. mediation in peace negotiations with the insurgents.

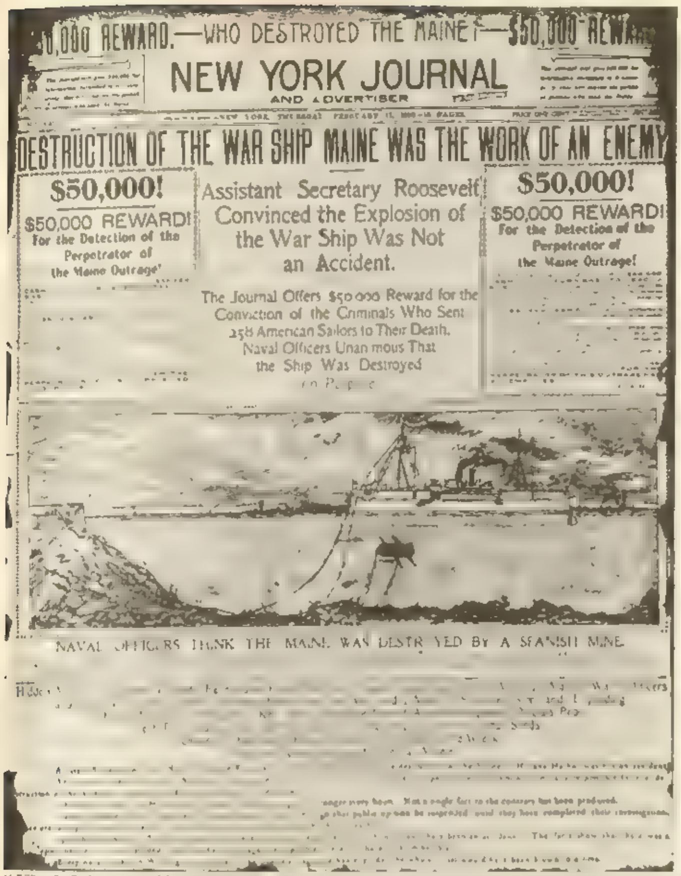
The Spanish government was caught upon the horns of a cruel dilemma. It had not readied its army or navy for war with the United States, nor had it warned the Spanish public of the necessity of relinquishing Cuba. War meant certain disaster. The surrender of Cuba might mean the overthrow of the government, perhaps of the dynasty. The ministry clutched at the only straws in sight. On the one hand, it sought support from the chief European governments. Aside from the British, these governments were sympathetic to Spain but were unwilling to give it more than weak verbal support. Their six ambassadors in Washington (including the British ambassador) called upon McKinley on April 6 and begged him in the name of humanity to refrain from armed intervention in Cuba. McKinley replied urbanely that if armed intervention should come, it would be in the interest of humanity. Meanwhile, Spain was going far in the acceptance of McKinley's terms of March 27—so far that the U.S. minister in Madrid, Stewart L. Woodford, assured his government that, granted a little time and patience, Spain could work out a solution acceptable to both the United States and the Cuban insurgents. Spain would end the reconcentration policy in fact as well as in name. Instead of accepting U.S. mediation, Spain would seek the pacification of the island through the Cuban Cortes, about to be elected under the autonomy program. Spain at first stated that an armistice would be granted only on application from the insurgents, but on April 9 announced one on its own initiative.

By this time, however, President McKinley had yielded to the war party in Congress. Brushing aside the Spanish concessions as unsatisfactory, he declared, in a special message to Congress on April 11, that "the war in Cuba must stop." From Congress he asked authority to use the armed forces of the United States "to secure a full and final termination of hostilities between the Government of Spain and the people of Cuba." Congress responded emphatically. In resolutions of April 20 it declared that "the people of Cuba are, and of right ought to be, free and independent," demanded that Spain at once relinquish authority over Cuba and withdraw its armed forces from the island, and authorized the president to use the army and navy of the United States to enforce that demand. A fourth resolution renounced for the United States any idea of annexing Cuba. As it was proposed by Sen. Henry M. Teller of Colorado, it came to be known as the Teller amendment. Upon being informed of the signing of the resolutions, the Spanish government at once severed diplomatic relations and on April 24 declared war upon the United States. Congress declared war April 25 and made the declaration retroactive to April 21.

The War.—The war thus begun was pathetically one-sided. Spain, as noted above, was in no sense prepared for war with a formidable power. Neither was the U.S. Army but the outcome of the war was dependent on sea power, and in this element the United States completely outclassed its opponent. Spain had nothing to match the four new battleships, "Indiana," "Iowa," "Massachusetts," and "Oregon," which formed the backbone of the North Atlantic squadron (the "Oregon" after her notable voyage from the Pacific coast). Even more superior to their antiquated antagonists at Manila were the protected cruisers of Commodore George Dewey's Asiatic squadron. Thanks largely to the energy and enthusiasm of the young assistant secretary of the Navy, Theodore Roosevelt, the U.S. ships had engaged in battle maneuvers and target practice and were well supplied with fuel and ammunition. Officers and men were confident and aggressive, whereas their Spanish opponents knew that they were doomed to defeat.

The first blow fell in Manila Bay, May 1, 1898. Commodore Dewey, picked by Roosevelt for the command, led his squadron into the bay before dawn and in a leisurely morning engagement destroyed the anchored Spanish ships by gunfire. American casualties amounted only to seven men slightly wounded. Dewey remained in control of the bay while a military force was sent out to assist him in taking possession of the city of Manila. By the end of July some 11,000 U.S. troops under Maj. Gen. Wesley Merritt had arrived in the Philippines, and on Aug. 13 they occupied Manila.

Meanwhile, attention had centred on Cuba. Upon the declaration of war a Spanish fleet of four armoured cruisers and three destroyers, commanded by Adm. Pascual Cervera, had steamed westward from the Cape Verde Islands. Its whereabouts remained unknown until late in May, when it was located in Santiago Harbour on the south coast of Cuba. The North Atlantic squadron under Rear Adm. William T. Sampson and the so-called Flying squadron under Commodore Winfield Scott Schley thereupon blockaded the harbour entrance. An army of regulars and volunteers (including Theodore Roosevelt's regiment of "Rough Riders," minus their horses) embarked at Tampa and landed on the Cuban coast east of Santiago. The American objective now was to catch Cervera between Army and Navy, thus forcing him either to surrender or to come out and fight. On July 1, in the hard fought Battles of El Caney and San Juan Hill, U.S. troops pene-



$50,000 REWARD.—WHO DESTROYED THE MAINE?—$50,000 REWARD.

DESTRUCTION OF THE WAR SHIP MAINE WAS THE WORK OF AN ENEMY

$50,000!

$50,000 REWARD! For the Detection of the Perpetrator of the Maine Outrage!

Assistant Secretary Roosevelt Convinced the Explosion of the War Ship Was Not an Accident.

The Journal Offers $50,000 Reward for the Conviction of the Criminals Who Sent 258 American Sailors to Their Death. Naval Officers Unanimous That the Ship Was Destroyed on Purpose.

$50,000!

$50,000 REWARD! For the Detection of the Perpetrator of the Maine Outrage!

NAVAL OFFICERS THINK THE MAINE WAS DESTROYED BY A SPANISH MINE.

(Left) Front page of *New York Journal* Feb. 17, 1898, announcing the sinking of the USS "Maine"; (above) mast of the sunken "Maine" in Havana Harbour; (below) U.S. Rough Riders crouch under fire; (top right) Maj. Gen. William R. Shafter leading forces into Santiago, July 17, 1898

(LEFT) THE GRANGER COLLECTION, (TOP CENTRE, TOP RIGHT) BROWN BROTHERS (BOTTOM) CULVER PICTURES

trated the outer defenses of Santiago. Their hold here was so precarious, and the incidence of malaria and other diseases was so widespread, that their commander, Maj. Gen. William R. Shafter, considered withdrawing to await reinforcements. This idea was abandoned when, on July 3, Admiral Cervera, under orders from Havana, led his squadron out of Santiago Harbour and tried to escape westward along the coast. In the ensuing battle all of Cervera's ships, under heavy fire from the U.S. fleet, were beached in a burning or sinking condition. American losses were insignificant. Two weeks later the city of Santiago surrendered to General Shafter.

The Peace.—The war was now over for all practical purposes, and on July 18 the Spanish government requested the good offices of France in arranging a termination of hostilities. Before the fighting ended, however, another American expeditionary force, commanded by Gen. Nelson A. Miles, occupied Puerto Rico. Armistice negotiations conducted in Washington ended with the signing of a protocol, Aug. 12, 1898. Besides ending hostilities, this agreement pledged Spain to surrender all authority over Cuba and to cede Puerto Rico and an unnamed island in the Ladrones (Marianas) to the United States. In the Philippines, Spain consented that the United States should occupy the city and harbour of Manila until the conclusion of a peace treaty that would determine the final disposition of the islands. Peace commissioners were to meet in Paris not later than Oct. 1.

The great question now confronting McKinley and his advisers was what, if anything, to demand of Spain in the Philippines. It seems certain that McKinley, in proposing intervention in Cuba, had had no thought of acquiring an empire on the other side of the globe; nor is there any reason to suppose that many members of Congress or of the public at large contemplated such an outcome of the war. Dewey's dramatic victory at Manila, however, had called sudden attention to a spot of great potential strategic importance. Theodore Roosevelt and his friend, Sen. Henry Cabot Lodge, devotees of the sea power doctrines of Capt. A. T. Mahan, saw in Manila Bay a base that might greatly enhance the sea power of the United States. Recent European aggressions in China seemed to many businessmen to threaten the American market. Manila appealed to them as a base from which U.S. interests in China could be defended. The Protestant churches saw the easy victory at Manila as a divine summons to missionary work in the Philippines. The British and Japanese governments, furthermore, let it be known that they would be pleased to see the United States keep the islands. There were difficulties about any other course. Restoration of Spanish rule promised only chaos similar to that from which Cuba had just been rescued: Nor did the Filipino people have the education, training, or experience needed for successful self-government, though an active group headed by Emilio Aguinaldo had actually proclaimed independence.

Swayed by these varied considerations and by his appraisal of popular sentiment, McKinley decided, after long deliberation, that the United States must take possession of the entire archipelago of about 7,000 islands and 7,000,000 inhabitants. This demand was reluctantly agreed to by Spain, with the stipulation that the United States should pay Spain $20,000,000, nominally for public buildings and public works in the Philippines. The treaty, signed Dec. 10, 1898, conformed to these terms. Spain relinquished Cuba and ceded to the United States the Philippines, Puerto Rico, and Guam in the Ladrones. The treaty was vigorously opposed in the U.S. Senate as inaugurating a policy of "imperialism" in the Philippines and was approved on Feb. 6, 1899, with a margin of a single vote. Two days earlier hostilities had begun at Manila between U.S. troops and Aguinaldo's insurgents. For over three years the Filipinos carried on guerrilla warfare against U.S. rule. (*See* PHILIPPINES, REPUBLIC OF THE: *History*.)

The Consequences.—The Spanish-American War, short as it was, and relatively inexpensive in both resources and human life, was an important turning point in the history of both antagonists. Though disastrous for Spain in immediate results, it was followed by a remarkable renaissance in Spanish life, both intellectual and material. As Salvador de Madariaga has written: "Spain felt then that the era of overseas adventures had gone, and that henceforth her future was at home. Her eyes, which for centuries had wandered to the ends of the world, were at last turned on her

own home estate." (Salvador de Madariaga, *Spain: a Modern History*, Frederick A. Praeger, Inc., New York, 1958.) There ensued two decades of significant progress in agriculture, development of mineral resources, industry, and transportation. At the same time there came to the front a brilliant group of thinkers and writers, the "Generation of 1898," who gave Spain a prominence in the intellectual and literary life of Europe that it had not enjoyed for centuries.

For the victorious United States the consequences were entirely different. It is a truism that the United States became a world power as a result of the war. It now had insular possessions in the Caribbean and stretching across the Pacific, including Hawaii, whose peaceful annexation had been hastened by the war. The war made certain that an American canal would be cut through the Isthmus of Panama. It stimulated enthusiasm for the Navy, which soon grew from fifth or sixth to second place among the world's war fleets. It prompted drastic reform in the U.S. Army, which had been poorly prepared for war and had lost far more men to disease than to enemy weapons. It also promoted the career of the nation's first world-minded president, Theodore Roosevelt. Within a few years the U.S. had made the Caribbean an American lake, was taking a leading part in the politics of the Far East, and was preparing in spite of itself to play a determining role in the affairs of Europe.

SPANISH LANGUAGE. Among the modern languages descended from Latin (*see* ROMANCE LANGUAGES), Spanish shows the greatest vitality and promise of future importance over a vast territory. In the Christian north of the Iberian Peninsula, the earliest Hispanic vernacular texts (glosses) go back to the 10th century, the first works of fine literature, displaying strong dialectal colouring, to about 1150. By 1270 Alfonso X the Wise, king of Castile and León, created standard Old Spanish. The late 15th century witnessed the introduction of preclassical Spanish. Classical Spanish, the vehicle of the Golden Age literature (*c.* 1530–1680), was followed by Modern Spanish.

Spanish is also known (paradoxically, more so in Latin America than in Spain proper) under the name of Castilian. Historically, this is a reminder of the fact that at the outset it represented merely one northern variety of Hispano-Latin folk speech. It emerged after A.D. 800 in Old Castile (around Burgos), then by the 11th century spread fanwise southward to New Castile (Toledo, Madrid) in the wake of the Christian "reconquest" and, especially after the merger of Castile with León and in the late 15th century with Aragon, became the official language of all Spain. In the peninsula, Castilian has gradually crowded out, except in secluded rural districts, the Hispano-Roman dialects of León, Asturias, Santander, Navarre, and Aragon.

In the south, where the Moorish occupation lasted generally until the early 13th century (much longer around Málaga and Granada), Western Arabic dialects were used among Muslims, while a strikingly archaic Hispano-Roman dialect ("Mozarabic") survived until about 1100 amid the dwindling Christian minority. Modern southern dialects (Extremeño, Andalusian, Murcian) represent prongs of Castilian overlying dimly recognizable earlier Romance speech forms.

The language of the 500,000 Spanish Jews (found chiefly in the Balkan Peninsula, North Africa, Israel, New York City, Buenos Aires), called Ladino or Judeo-Spaniolic, is based squarely on 15th-century Spanish, containing heterogeneous admixtures. Portuguese, in the extreme west, and Galician, confined to the northwest, jointly form a language apart, with close grammatical and lexical, but not phonic, ties to Spanish. In the northeast, Catalan, including Balearic and diluted Valencian, constitutes a separate Romance language, influenced by Provençal. Basque, a relic of a pre-Indo-European family, straddles the western Pyrenees.

Outside the peninsula, Spanish is spoken or understood in virtually all South America except Brazil, in most of continental and insular Central America, in the Canary Islands, in the Tangier zone and adjoining sections of Morocco, along stretches of the Atlantic coast of equatorial Africa, and, on a decreasing scale, in the Philippines. Its hold on the New World is secure: if it has yielded ground to Portuguese in southern Brazil and is retreating before English in California, Arizona, New Mexico, Colorado, and Texas, it is steadily gaining ground, by compensation, in areas long dominated by indigenous Indian languages (Paraguay and the Yucatán Peninsula of Mexico are characteristic bilingual zones) and is eagerly accepted by immigrants' families in Buenos Aires and Montevideo. The influx of Cubans and, later, Puerto Ricans has made Spanish the second-ranking language in the New York metropolitan area. The latest political events have brought another wave of Cuban refugees to southern Florida.

Phonology and Orthography.—The sound system is characterized by five sharply delineated, short to medium-length vowels, lacking relevant variants (*i, e, a, o, u*). Two important rising diphthongs (*ie, ue;* also, only after *c, ua*), typically confined to the stressed syllable, outbalance several infrequent falling diphthongs (*ai, au, ei, eu, oi, ui*). Consonants, except for *n* in special cases (*ennoblecer, perenne*), are not doubled: *abad, Meca, ilustrar; rr* intervocalically contrasts with *r* (*perro* ~ *pero*), forming with *r* word-initially (*rey*) and after *n, s* (*Enrique, Israel*) a separate sound normally produced by five vibrations of the tongue. Voiceless stops (*p, t, k;* the last spelled mostly *c* or *qu*, according to environment) are uttered virtually alike in all positions. The corresponding voiced stops *b, d, g* are reduced to spirants between vowels, as in *abogado*. The typical syllable consists of consonant plus vowel; hence few consonants occur word-finally (*-d, -l, -n, -r, -s, -z*, anciently also *-ch, -ll, -ñ*, etc.); of these, *-d, -n, -r*, and especially *-s* are inflectionally important. Dialect speech goes further, allowing *-d, -r, -s* to disappear, or *-l* and *-r* to merge.

Until *c.* 1600, Spanish contained a greater variety of consonants: *x* in *exe* (mod. *eje*) equaled English *sh*, *j* in *ojo* was like *z* in English "azure" (these two merged, and their product became [χ], like *ch* in German *Bach*). The affricates *ç* [=ts] and *z* [=dz] collided; their amalgam was pronounced either [θ], like *th* in "thin" (most of Spain), or like voiceless *s* in "mass" (part of Andalusia, Spanish America); nowadays, *c* before *e, i*, and *z* otherwise are merely variant spellings of the same sound, as are also *g* before front vowels and *j*. The lone remaining affricate *ch*, pronounced as in English, represents a unit phoneme and ranks as a separate letter. Voiced *s*, as in English "as," became voiceless between vowels (*casa*), surviving where adjacent to another voiced consonant (*desde*). The [v] sound, as in Old Spanish *bever, Córdova*, has disappeared; today *v*, tolerated for historical reasons, duplicates the orthographic role of *b:* both letters represent the same sound, released as a stop or as a spirant according to its position. Colloquially, palatal *l* (conventional spelling, *ll*, rated as a single letter) tends to become the semiconsonant [*j*], more rapidly so in the new world than in Spain.

Noteworthy are the traditional frequency of *a* and *s* and the infrequency of stops and of *f* (compare *hijo* "son" with its counterparts *filho, fils, figlio*, etc., in cognate languages). The sound [h], absent from standard Spanish, occurs dialectally, in local equivalents of words like *holgar* and *ojo*. Hence the letter *h* is predominantly ornamental, being used in deference to Latin tradition (*hora*) or as a holdover from earlier native practice (*hierro*, from older *fierro*); it is functional only in the segment *hue-*, where its role is comparable with that of mute *u* in *gue-, gui-*, and as an ingredient of *ch*.

Grammar.—Inflection, derivation, composition, and syntax show the typical features of a conservative Romance language, pointing up its resemblance to Portuguese, Old (but not Modern) French, and Italian as regards, for instance, the sparing use of definite and indefinite articles and of subject personal pronouns, the scope of imperfect and preterit, the formation of future and conditional, the partial dependence of the gender on the final vowel. Pronouns alone show traces of declension (*yo, me, mí*) and, originally of the "neuter" (*lo mío, lo otro;* secondarily, *lo bueno*). Plural formation depends on interplay of termination and accen-

tual pattern (*hombre-s, mujer-es, cortés ~ corteses, lunes* invariable). Nouns and pronouns in *-o* produce feminines in *-a;* otherwise the feminine is more sharply characterized in substantives (*vendedor-a*) and in adjective-substantives (*trabajador-a*) than in pure adjectives (*cortés* invariable).

The conjugation is based on a closely integrated system of tenses (simple or compounded with *haber*) and moods (indicative, subjunctive; the latter suggesting uncertainty or purpose); the reflexive construction has overlaid the passive voice. Peculiarly modern are the almost interchangeable use of two past subjunctives (*-se, -ra*) and the obsolescence of the future subjunctive. The only productive conjugation class is *-ar;* for verbs derived from substantives: *-ear* (*telefonear*); the *-er* and *-ir* verbs form closed groups. Stray relics of the Latin paradigm are found among "strong" (=radical-stressed) preterits (*dije, hice*) and past participles (*dicho, hecho*).

Spanish strikes the speaker of English through its extraordinary wealth of derivational models, a feature in which it equals Italian and surpasses French by a wide margin. Abstracts, for instance, can be derived from adjectives in a wide variety of seemingly unpredictable ways: *pobre* → *pobr-eza* "poverty," *mudo* → *mud-ez* "dumbness," *sordo* → *sord-era* "deafness," *calvo* → *calv-icie* "baldness," *avaro* → *avar-icia* "avarice," *pleno* → *plen-itud* "fullness," *pesado* → *pesad-umbre* "heaviness," *bizarro* → *bizarr-ía* "gallantry," *glotón* → *gloton-ería* "gluttony," *loco* → *loc-ura* "madness," *verde* → *verd-or* (poetical) "greenness"; and there exist comparably elaborate devices to transform a verb into an abstract, to extract a female agential from its male counterpart, to designate a fruit tree or an orchard using as the basis the name of the specific fruit or vegetable, etc. The typical diminutive suffix is *-ito, -ita* (*cas-ita, señor-ita*) in preference to older *-illo*, but some dialect speakers favour *-ino, -ico*, or *-uco*, while for names of young animals, especially whelps, one finds also *-ezno* and *-ato*, hence *lob-ezno* "wolf cub" beside *ballen-ato* "whale calf." Prefixes, all Latin in origin, are few, colourless, and by and large confined to verbal stems: *a-, des-, en-, entre-, es-* (*ex-*), *re-, so-, sobre-, tras-;* rarely *ante-, per-, pos-*. Compounds are on the wane, except for the one pattern *matafuego* "fire extinguisher" (literally "killfire"; *cf.* English *killjoy, lack-luster*), *rascacielos* "skyscraper."

Vocabulary.—Viewed in the historical (stratigraphic) perspective, only a handful of important Spanish words, including some animal names, may be safely ascribed to the chronologically oldest layer, having been absorbed by Hispano-Romans from the language of ancestral Iberians and Celtiberians or of neighbouring Basques; *e.g., ard-illa* "squirrel," *bruja* "witch," *izquierdo* "left," *perro* "dog," *pizarra* "slate," *zorro* "fox." The core of the lexicon consists of a relatively archaic layer of Latin words, reflecting (frequently in contrast to French and to Italian) the preference of colloquial Latin throughout the last two centuries of the Republic; characteristic are *hermoso* "beautiful" as against French *beau*, Italian *bello; arena* "sand" as against French *sable*, Italian *sabbia; día* "day" as against French *jour*, Italian *giorno;* and *comer* "to eat" as against French *manger*, Italian *mangiare*. Moreover, Latin, as the medieval language of church, administration, and scholarship, contributed numerous learned and semilearned words, which show "retarded" sound development, having skipped certain evolutionary stages; *e.g., iglesia*, Old Spanish *eglesia* "church." Since the early days of humanism, there has been an incessant flow of Latinisms and Hellenisms into Spanish, less numerous, however, by a considerable margin than those absorbed into English (thus, Spanish lacks counterparts of "obstreperous" and "preposterous" and infrequently uses those of "acrimonious" and "exacerbate").

Additional lexical strains that have contributed to the present wealth of the Spanish vocabulary are traceable to Gothic (*hato* "herd," *ropa* "clothing," *brotar* "to sprout," and numerous proper names, including *Alfonso, Fernando*, and *Elvira*); to Byzantine Greek (*botica* "drugstore"); to Arabic (frequently recognizable by the initial segments *al-, a-* or the termination *-í: al-calde* "mayor," *a-zucena* "lily," *balad-í* "frivolous," "paltry"); and to Old French and Old Provençal, especially words relating to the monastic and the chivalrous or courtly spheres (*monje* "monk," *fraile, Fray, Frey* "friar," *ruiseñor* "nightingale," *vergel* "flower and fruit garden" and others ending in *-el*).

Italian was very influential in the period 1450–1625, supplying hundreds of specific terms which, in many instances, continue to be used in numerous arts, crafts, and trades, such as painting, navigation, and banking. French reached the peak of its influence in the 18th century (when the controversial Afrancesados introduced short-lived *remarcable, retornar*, etc.). English, in particular U.S., civilization began to colour the lexicon of sports, science, commerce, and politics after 1900. Over the centuries, the indigenous New World languages have supplied only terms in restricted domains (mostly fauna and flora).

The Royal Spanish Academy has exercised a restraining influence on the spontaneous development of the language through the 18 successive editions of its dictionary, much less so through its normative grammar, at no time nearly so influential as A. Bello's and V. Salvá's. Of late, the national academies of the Spanish American countries have established a salutary rapport with the Madrid Academy.

(Y. M.)

SPANISH LITERATURE. The literature of Spain falls into three divisions according to language: Castilian, Catalan, and Galician (*see* SPANISH LANGUAGE; PORTUGUESE LANGUAGE; CATALAN; GALICIA). This article provides a brief historical account of the development of each of these three literatures. For the historical background, *see* SPAIN: *History;* and articles on the main kingdoms and provinces of Spain (*e.g.*, ARAGON; CASTILE; CATALONIA; LEÓN). For the literature of the former Spanish colonies in the Americas, *see* IBERO-AMERICAN LITERATURE. *See* also biographies of many writers mentioned; the general articles DRAMA: *Modern Drama* and NOVEL: *Early Modes of Narrative and the Novel;* and articles on other forms, such as SATIRE and SONNET.

Although literature in the vernacular did not begin to be written until the medieval period, Spain had already made considerable contributions to literature. The two Senecas, Lucan, Martial, Quintilian, and Prudentius are among writers in Latin who lived in,

or were born in, Spain before the separation of the Romance languages (*q.v.*). For their writings, *see* LATIN LITERATURE. Later, the writings of Spanish Muslims and Jews form an important branch of Arabic and Hebrew literature (*qq.v.; see* also JEWISH PHILOSOPHY).

This article is divided into the following main sections:

I. CASTILIAN LITERATURE

A. MEDIEVAL PERIOD

1. The Beginnings of Vernacular Literature.—By the time of the Muslim invasion (beginning in 711), the Latin spoken in the Iberian Peninsula was in process of transformation into Romance. The 10th-century *Glosas emilianenses* and *Glosas silenses* —marginal notes in a vernacular in manuscripts belonging to the monasteries of San Millán de la Cogolla and Silos, in La Rioja, and preserved in the Academia de la Historia, Madrid, and the British Museum, London, respectively—reveal traces of a vernacular already substantially developed. Mocádem, a blind poet living near Córdoba at the beginning of the century, was recorded 200 years later as having taken "expressions in vulgar Arabic or Romance, called them *markaz,* and built on them his *zéjels* or *muwashshahs.*" As a result of research since 1948, numerous examples of the *markaz* (theme stanza), written in a Romance idiom transliterated into Hebrew or Arabic, have been recovered from Hebrew and from Arabic *muwashshahs* (*q.v.*) from the 11th century onward. These provide not only the earliest texts in Mozarabic (the Romance dialect of Spaniards living under the Muslims) but also evidence of a popular poetry that may have begun in the time of Mocádem or earlier: they can now be seen to explain much in the traditional Spanish lyric types (*e.g.,* the *villancico,* "carol") of the later Middle Ages and the Renaissance. The *markaz* as a whole was generally a love song sung by the woman (comparable to the later Galician *cantiga de amigo; see* PORTUGUESE LITERATURE), and the motif, in Romance, was a cry of passion on which the whole poem was an elaboration or up to which it led.

2. The Rise of Heroic Poetry.—The earliest surviving monument of Spanish literature, and one of its most distinctive masterpieces, is the *Poema* (or *Cantar*) *de mío Cid,* an epic poem (*cantar de gesta*) of the mid-12th century (the existing manuscript is an imperfect copy of 1307). This work, of 3,735 irregular lines (of 11–18 syllables, with marked caesura and traces of a four-beat accentual rhythm), grouped in assonating *laisses,* tells of the fall from and restoration to royal favour of the Castilian noble Rodrigo Díaz de Vivar (*c.* 1043–99) known by the Arabic title of *sidi* ("lord"). The historical setting and personages, the topographical detail, the realism of tone and treatment, and the proximity in time of the anonymous poet to his hero have made possible the advancing of "historicity" as a first characteristic of this poem, and of the Castilian epic in general. The latter two of its three *cantares* (sections), however, while as convincing in detail as the first, are untrue to recorded history; the conception of the whole work is essentially poetic and handled with much imaginative artistry; and the according of a mere seven lines to the Cid's greatest achievement, the taking of Valencia from the Muslims after a nine-months' siege in 1094, makes it clear that the scale of values is subjective. The poem caught the popular imagination and lived on in epic, chronicle, ballad, and drama, helping to fix the popular conception of the Castilian character. The only other surviving epic text (apart from a 100-line fragment of uncertain filiation on *Roncesvalles,* of the early 13th century; *see* ROLAND, CHANSON DE) is the wholly fanciful and decadent 14th-century *Cantar de Rodrigo* (also called the *Crónica rimada*), telling of the Cid's early manhood; it was from this that the later legend of the Cid took shape. (*See* also CID, THE.)

Frequent allusions in vernacular chronicles to the heroic narratives of minstrels (*juglares*) make it clear that the *mester de juglaría* ("minstrel's craft") was much richer than the scarcity of manuscripts would suggest. Thanks to the vernacular chronicles, which, from their beginning late in the 13th century, accepted these narratives as being of historical validity and "prosified" them at length, it has been possible to reconstruct the themes and even some fragments of the text of epics on *Los siete Infantes de Lara* ("The Seven Princes of Lara") and *Fernán González* (both set in the 10th century; the first about seven brothers who were betrayed by their uncle, killed in battle, and later avenged; the second about a Castilian hero; *see* below); *El Cerco de Zamora* ("The Siege of Zamora"; again involving the Cid, and perhaps artistically the best); and others. *Bernardo del Carpio,* about a fictitious Spanish warrior who helped to defeat Roland at Roncesvalles, provides a hero in defense of Spanish prestige against the French Carolingian epic; the other themes are an integral part of the feudal history of 10th- and 11th-century Castile, close to the time of telling and less probably related in their origins to the very different French epics (*chansons de geste; q.v.*) than to a remote Visigothic past.

3. Learned Narrative Poetry.—A new school of erudite poetry, much indebted to France and linked not with the itinerant *juglar* reciting to popular audiences but with the monastery and a literate public, became known as the *mester de clerecía* ("clerkly craft"). Regularly adopting the French Alexandrine in the set mold of the *cuaderna vía* ("fourfold way," *i.e.,* four-line single-rhyme stanza with a 14-syllable line), and dealing with religious, didactic, or pseudohistorical matter, it was a product of the study. It is best and probably first exemplified in Gonzalo de Berceo (*c.* 1195–*c.* 1268), the earliest Spanish poet known by name. Apologizing for inadequate Latinity, he versified unwearyingly in the vernacular the lives of Spanish saints, the miracles of the Virgin, and other devotional themes with an ingenuous candour and an accumulation of picturesque and affectionately observed detail that largely atone for his prolixity (about 13,000 lines) and fidelity to his sources. Also of the 13th century and in the same form are the *Libro de Alexandre* (*see* ALEXANDER ROMANCES), much more erudite and pretentious; the *Libro de Apolonio,* a version of the Latin romance on Apollonius of Tyre (*q.v.*); and the *Poema de Fernán González,* a clerical reworking of a lost epic on the 10th-century count of Castile who won its independence from León.

4. The Beginnings of Prose.—A major influence on prose was exercised by Arabic. The gates of Oriental learning and story were opened to Spain by the capture (1085) from the Muslims of Toledo, which became a centre of translation from Oriental languages. In 1120 Pedro Alfonso (Petrus Alfonsi, Rabbi Moisés

Sefardí), an Aragonese Jew converted to Christianity, introduced Eastern fable to the non-Arabic reader with his *Disciplina clericalis*, a collection of tales, with ethical instruction, translated into a barbarous Latin. The anonymous translation from the Arabic (1251) of the "beast fable" *Kalila e Dimna* is the first essay in storytelling in the Spanish language. (*See* also FABLE; BIDPAI, FABLES OF.) The Oriental romance of the Seven Sages, or Seven Wise Masters (*q.v.*), was translated from a Latin text as the *Libro de los engannos e assayamientos de las mujeres* (1253; also known as the *Sendebar;* Eng. trans., *The Book of the Wiles of Women,* 1956). Other collections of Eastern stories followed.

5. Alfonso the Wise.—The middle of the 12th century saw the recovery of Córdoba, Valencia, and Seville by the Christians, the kingdom of Granada alone remaining in Muslim hands. An indication of the more propitious intellectual atmosphere resulting was seen in the founding of universities (*e.g.,* Salamanca *c.* 1218; charter, 1243); and under the stimulus of Alfonso X of Castile and León (Alfonso the Wise [*El Sabio*]; 1252–84) literature achieved official prestige. Alfonso, in whose chancery Castilian replaced Latin as the language for public documents, may be described as the father of Castilian prose. He organized a vast enterprise of translation and compilation aimed at fusing in the vernacular all available knowledge, classical, Oriental, Hebrew, and Christian. The works undertaken, often under his personal editorship, included the great legal code *Las siete partidas,* published in sections, a mine of information on the life and customs of the time, and compilations from Arabic sources such as *Los libros del saber de astronomia, Los tablas alfonsíes* (on astronomy), *El lapidario* (a treatise on the magical properties of precious stones), and *El libro de los juegos* (a famous medieval work on games, especially chess). With *La primera crónica general* (or *Crónica general*), covering the history of Spain from its first settlers, and the *General Estoria,* an attempt at a universal history from the Creation, Alfonso was the founder of Spanish historiography.

The *Crónica general,* carried by Alfonso to A.D. 711 and completed by his son, Sancho IV, gave rise to a series of chronicles over the two centuries following and was the most influential single work of the Spanish Middle Ages; the *General Estoria* did not reach later than the parents of the Virgin Mary. Himself a poet, Alfonso was responsible too for one of the greatest collections of medieval poetry and music, the *Cantigas de Santa María,* in Galician (then the accepted language for lyric; *see* below).

6. The 14th Century.—The period of translation and compilation was succeeded by one of brilliant original creation. It is best represented in the prose of Alfonso's nephew, the infante Don Juan Manuel (1282–1348?), and in the poetry of Juan Ruiz (*c.* 1283–*c.* 1350), archpriest of Hita. Juan Manuel's *Libro de los exemplos del Conde Lucanor et de Patronio* (1323–35), a collection of 50 moral tales, still drew heavily on Arabic sources; but by its individuality of style and treatment it ranks high in the beginnings of Spanish fiction.

Earlier, under the influence in part of the Arthurian, or Breton, cycle (*see* ARTHURIAN LEGEND), which from the turn of the 13th century had been circulating in Spain in translation, there had appeared (*c.* 1305) the first Spanish romance of chivalry (*libro de cabellaría*), and the first full-length Spanish novel, *El caballero Cifar,* on the Eustace theme (*see* ROMANCE). Cifar's squire, Ribaldo, is a distant precursor of Don Quixote's Sancho Panza, and thus an early token of the constant impinging of the real on the ideal so characteristic of Spanish literature. Probably at about the same time there was circulating the famous *Amadís de Gaula* (*q.v.*), a chivalric romance also related to the Arthurian cycle, and destined to father a progeny that held the imagination of kings, courtiers, and scholars throughout the 16th century. Sentimental idealism, lyrical atmosphere, and supernatural adventure notwithstanding, the traditional ascription of this to Portugal (*see* PORTUGUESE LITERATURE) is, at best, inconclusive. The author may have been a Galician or Portuguese troubadour in exile at the Castilian court.

Juan Ruiz, a man of the people, was the most intensely alert

THE LITERARY COURT OF ALFONSO THE WISE

The first illumination from a 13th-century manuscript of the *Cantigas de Santa María,* a collection of medieval poetry and music compiled by Alfonso X

and individualized of early writers. His *Libro de buen amor* (1330; expanded, 1343) represents a collection of disparate elements—Ovid, Aesop, the 12th-century Latin *Pamphilus de amore,* the 13th-century *Carmina Burana,* and the liturgy—with a strong suggestion of Muslim ways of thinking in the mingling of eroticism with devotion, and the invitation to the reader to interpret for himself the author's equivocal teachings. But this diversity of adventure was presented as a satiric autobiography and stamped with the author's exuberant personality; and his Trotaconventos, ancestress of La Celestina (*see* below), is the first great character creation in Spanish literature. The dominant metre was still the *cuaderna vía,* handled with a new narrative vigour and plasticity; but the interspersing of the text with lyrics, religious, pastoral-farcical, amorous, or satirical, of great metrical variety, pointed to its approaching supersession.

Continuing evidence of the exotic strands that were being woven into the texture of Spanish literature may be found in the anonymous *Poema de Yuçuf* (also assigned to the 14th century), and in the *Proverbios morales* (*c.* 1355) of Šem Tob ibn Ardutiel ben Isaac (Santob de Carrión de los Condes; *c.* 1290–*c.* 1369). The former, an Aragonese version in *cuaderna vía* of the story of Joseph, is based not on the Bible but on the Koran, and is written in Arabic characters; it is the chief representative of the so-called *aljamiado* ("barbarian") literature, Spanish in language, Arabic (or Hebrew) in tone and script. The *Proverbios* of Šem Tob, comprising 725 Alexandrine couplets with internal as well as end rhyme, introduced to Spanish the grave sententiousness of Hebrew poetry with its extreme aphoristic concision; his chief sources were the Old Testament, the Talmud, and the Hebrew poet and Arabic philosopher Ibn Gabirol.

The chancellor of Castile, Pedro López de Ayala (1332–1407), dominates the later part of the 14th century both in poetry—with his *Rimado de palacio,* the last major relic of the *cuaderna vía,* the 8,200 lines of which distilled the essence of a lifetime of experience and disillusion in high places—and in prose as a his-

torian of things seen. His chronicles (the last incomplete) of the reigns of Peter I (Pedro the Cruel), Henry II (of Trastámara), John I, and Henry III of Castile infused new life into the tradition of the Latin *cronicón*, which dates back in Spain to the 5th century, and greatly stimulated the writing of personal, contemporary history. An early Humanist, he translated and imitated Livy and Boccaccio, Boëthius, St. Gregory, and St. Isidore.

7. The 15th Century.—The early 15th century witnessed a tentative renewal of poetry under Italian influence. The contrast is strong, during the reign of John II (1406–54), between the social anarchy of a feudalism in its death throes and the cultivation of polite letters, which was becoming an expected mark of birth and breeding. Collections such as the *Cancionero de Baena*, made for the king in 1445 by Juan Alfonso de Baena (a converted Jew, and himself a poet), containing 583 poems by 55 poets ranging from the highest nobles to the humblest versifiers on the fringes of their service, show not merely the decadent tradition of the Galician-Portuguese troubadour school but also the new stirrings of a much more intellectual poetry using symbol, allegory, and classical allusion in the treatment of themes of high moral, philosophical, or political intent. Francisco Imperial, son of a Genoese settled in Seville, and a leader of the new poetry, drew on Dante to present a challenge taken up by the marqués de Santillana (1398–1458), whose work was included in the *Cancionero;* Juan de Mena (1411–56); and others. Santillana, poet and scholar, soldier and statesman, was a collector of the masterpieces of foreign literatures and a stimulator of translation. His *Proemio e carta al condestable de Portugal* ("Preface and Letter to the Constable of Portugal"; 1449), the earliest work of literary history and criticism in Spanish, draws on his reading in contemporary foreign languages, and in the translated classics. Imperial had already sought to acclimatize the Italian hendecasyllable. Santillana's 42 sonnets *"fechos al itálico modo"* (*i.e.*, in the Italian style) marked the beginnings of the formal enrichment of Spanish poetry at the dawn of a new age. His role as precursor is still outstanding, though his sonnets, like his long poems *La comedieta de Ponza*, *El diálogo de Bias contra fortuna*, and *La defunción de don Enrique de Villena*, in thought and structure likewise showing the poet at school in Italy, are neglected in favour of his charming *canciones*, *decires*, and *serranillas* (rustic songs describing an encounter between a nobleman and a mountain girl) of native inspiration.

Juan de Mena's vast allegorical poem of the drama of history past, present, and to come (*El laberinto de fortuna*, 1444) was a more conscious attempt to rival Dante; felicitous often in isolated narrative passages on Spain's heroic past, it is weighed down by pedantry, and by over-Latinization of syntax and vocabulary. His metre, the common vehicle of learned poetry throughout the 15th century, is the *verso de arte mayor*, characterized less by its variable length (9–14 syllables, with 12 as the norm, divided into two parts of 6 each) than by its two hemistichs and strong ternary rhythm; accentual verse is not found again in Spanish until the 19th century. The other outstanding 15th-century poet is Jorge Manrique (1440?–79), who achieved immortality with one elegiac poem, *Coplas por la muerte de su padre* (1476).

An outstanding anonymous poem of the early part of the 15th century, the *Danza de la muerte*, is the finest extant example of a kind popular in the Middle Ages with poets, painters, and composers—the Dance of Death (*q.v.*). It is related to the earlier *Danse macabre* at Paris, but is written with greater satiric force, and introduces characters (*e.g.*, a rabbi) not included in the French cycle. Consisting of 79 *coplas de arte mayor* (*i.e.*, stanzas of 8 lines, each of 12 syllables), it is in the form of a dialogue between inexorable death and his protesting victims—who range from pope and emperor, king and cardinal, to lawyer's clerk and humble cleric, and so present a cross-section of society. Although not intended for dramatic presentation, it formed the basis for later drama.

In prose the age saw the first Spanish books of travel, notably an account of a journey to Samarkand in 1403–06 (*Vida del gran Tamerlán*) by Ruy González de Clavijo (d. 1412), who had gone there as Henry III's ambassador; and an account of the travels in Europe and the Middle East (1435–39) of Pedro Tafur (*Las andanças e viajes por diversas partes del mundo* ["Adventures and Journeys in Different Parts of the World"]). Contemporary history took on a biographical dress in two admirable collections of portraits of eminent Castilians: *Generaciones e semblanzas* ("Generations and Biographical Sketches"; the third, and only original, part of a larger *Mar de historias* ["Sea of Histories"], written *c.* 1450; published 1517), by Fernán Pérez de Guzmán (*c.* 1376–1460), and the *Libro de los claros varones de Castilla* ("Book About Distinguished Castilian Men"; 1486) of Hernando del Pulgar (1436–93).

B. The Renaissance and the Siglo de Oro

1. The Beginning of the Golden Age.—The unification of Spain in 1479 under the "Catholic kings," and Columbus' discovery of the New World (1492), following the introduction of printing (1474), and concurrent with the full play of cultural traffic with Italy (where Naples had been since 1443 a dependency of Aragon), may be taken as opening the era of the Renaissance in Spain. With the exception of the more popular veins associated with oral tradition, the medieval poetic achievement lapsed into oblivion: the *Poema de mio Cid* and the corpus of the *mester de clerecía* were not printed until 1779; the mid-12th-century *Auto de los reyes magos* (*see* below) not until 1863. National heroic themes survived through ballad and chronicle, early beneficiaries of the printing press.

What gave Spanish literature its distinctive mark in this period (the *siglo de oro*—Golden Age) was, however, the wealth of new experience born of overseas adventure, reflected in historical and scientific writing and in the detached and questioning attitude, so strikingly exemplified in the theatre, to the rediscovered norms of classical authority. The first Spanish Humanists were also the first grammarians and lexicographers of any Romance tongue: Antonio de Nebrija's grammar of the Castilian language (1492) was written under the sense of impending imperial responsibilities. Juan Luis Vives (1492–1540), a figure of European eminence, the brothers Juan (*c.* 1498–1541) and Alfonso (d. 1532) de Valdés, and others among the best brains and noblest minds of contemporary Spain were friends or followers of Erasmus (*q.v.*), whose writings circulated in translation from 1520 until their suppression after his death in 1536, and whose influence has been seen in St. Ignatius of Loyola, and, later, in Fray Luis de León (*see* below).

The masterpiece of the early Renaissance is the *Tragicomedia de Calixto y Melibea* (1499), a novel in dialogue form published anonymously but generally attributed to a converted Jew, Fernando de Rojas (d. 1541). The dominant character, a go-between elaborated from Juan Ruiz's Trotaconventos and depicted with a realism unsurpassed in Spanish letters, soon caused the work to be rebaptized, after her, *La Celestina* (*q.v.*), thereby obscuring its significance as a tragedy of idealism in the new world of the senses liberated by the Renaissance. The analysis of passion and the dramatic conflict with nemesis that its pursuit involves were worked out with such psychological intensity on the intersecting planes of the noble and the ignoble, of medieval and Renaissance, as to make this the first masterpiece of Spanish prose.

2. Romancero.—Spanish ballads (*romances*) form the strongest link in a chain of tradition from medieval heroic epic to 20th-century poetry and drama; they lie at the heart of the national

consciousness; and their expansion and capacity for survival, from Salonika to Chile, from the Low Countries to North Africa, reflect the far-flung boundaries of Spain's prestige in its age of greatness. The ballad form is clearly defined: the 16-syllable line divided into two equal hemistichs (or two octosyllables), with a single assonance, suggests a regularizing of the old epic versification, though it is doubtful whether (as some scholars have claimed) it may be inferred from this that the *romancero* originated in the fragmentation of the decadent epic. The earliest datable *romances* treat of frontier incidents (late 14th century) or lyrical themes (early 15th century), and it has been shown that only 5 out of about 35 "old" *romances* of the Cid bear relation to known epic sources, while two-thirds of the whole vast corpus are lyrical and betray French or other foreign influence. It is on the ballads on medieval heroic themes, nevertheless, that the peculiar importance of the kind in Spain hinges: they formed everyman's source book on national history and the national character. Circulating first as *pliegos sueltos* (*i.e.*, "broadsides") the traditional ballads were collected in the *Cancionero sin año* (printed at Antwerp, *c.* 1550) and in the *Silva de varios romances* (3 parts, 1550–51), and thereafter repeatedly. Soon the form was exploited for lyrical purposes in the *romances artísticos* of the most famous poets of the age, to remain the chosen medium for popular narrative verse.

3. Early Drama.—The origins of drama in Spain may be presumed, in default of evidence, to have been like those of drama in France and England, originating in the liturgy (*see* DRAMA: *Medieval Drama*). The *Auto de los reyes magos*, an incomplete play belonging to an Epiphany cycle from the mid-12th century, is the only surviving text of medieval Spanish drama, and the second surviving liturgical dramatic text in any vernacular (the first being the French *Jeu d'Adam* of the early 12th century). It is extant in a single 13th-century manuscript, and was apparently based on an earlier liturgical play written in Latin in Orléans, since it resembles it, and differs from other Epiphany plays, in some important respects (*e.g.*, that the three magi are introduced separately). The characterization of the magi, of Herod, and of his advisers is realistic; and the way in which the verse is manipulated foreshadows, although imperfectly, the later development of the drama in Spain.

That there was a tradition of liturgical drama in the vernacular may be inferred from references in legal and other documents, and a reference in Alfonso X's legal code (*Las siete partidas*, *c.* 1255; *see* above) encouraging the clergy to take part in liturgical plays, but forbidding their participation in *juegos de escarnios* (*i.e.*, burlesque pantomimes of sacred subjects) suggests also the existence of some form of secular drama, but no texts have survived. However, these *juegos*—short, satiric entertainments given by traveling players in marketplaces, or outside churches—were the forerunners of the later *farsas*, and of the numerous short plays and interludes—*paso, entremes, sainete*, etc.—that form one of the main Spanish contributions to dramatic genres.

Juan del Encina (1468–1529?) marked the first stage in the emancipation of the drama from ecclesiastical leading strings by way of performances for a noble patron. The *representaciones* and *églogas* in his *Cancionero* (1496) are pastoral-religious dramatic dialogues, in a rustic dialect, *sayagüés*, later accepted as a convention in comic pastoral; but he soon turned to the debating of purely secular themes or to vividly depicted farce. Three of his plays dating from a long stay in Italy (the *Églogas de Zambardo*, *de Cristino y Febea y Cardonio*, and *de Plácida y Vitoriano*) show Encina's conception of drama transformed by his Italian experience from ingenuous medievalism to bold Renaissance experimenting in the realm of sensuous indulgence, fortified by classical myth and allegory.

Encina's Portuguese disciple Gil Vicente (*c.* 1465–*c.* 1537), a court poet at Lisbon who wrote 11 of his plays entirely, and 17 partly, in Castilian, showed a great advance in naturalness of dialogue, acuteness of observation, and humour of situation. His weakness lay in plot, his distinction in a lyricism that expressed itself in the finest Spanish poetry of the period, and in a vivid, plastic representation of allegory that looks forward to Calderón. Bartolomé de Torres Naharro (1484?–1520?) went to Naples, and published there in his *Propalladia* (1517) six of his eight comedies, all performed before a noble audience. These show a sense of plot and a first awareness of dramatic theory, with a division in form into five acts (soon to be reduced to three) and in kind into *comedias á noticia* and *á fantasía* (the former realistic, as the *Comedia soldadesca* and the *Tinellaria*, satirizing respectively an army of occupation and the servants' hall in a cardinal's palace; the latter romantic). The *Serafina* and the *Ymenea* are of particular interest as foreshadowing the "cloak-and-sword" comedy, with the *pundonor* ("point of honour") as theme.

The emergence of the drama from court and nobleman's house to the marketplace and the creation of a public were largely the work of Lope de Rueda (*c.* 1510–65), who toured Spain with his modest troupe, his still more modest properties, and a repertoire of his own composing. His four prose comedies all owned Italian models and were clumsy in construction; it is in the ten *pasos* (comic interludes performed between the acts of longer plays) that his dramatic merit resides, and with it the distinction of fathering the one-act play which, constantly renewing itself, has some claim to be regarded as the most living and popular dramatic form in Spain.

The first dramatist to realize what might be made of the *romancero* in the theatre, in the sense of stirring the public's most responsive chord, was Juan de la Cueva (1543?–1610). Most of his 14 comedies and tragedies were taken from classical antiquity and written in the manner of Seneca, but in three (*Los siete infantes de Lara* ["The Seven Princes of Lara"], *El reto de Zamora* ["The Challenge of Zamora"], *La libertad de España por Bernardo del Carpio* ["The Liberation of Spain by Bernardo del Carpio"]) he turned to themes of Spain's early heroic story, already familiar in ballad, and thereby set an example that accounts in large part for the immense fertility of the *comedia*, and for the close accord thenceforth established between dramatist and public. He was not an accomplished dramatist, but he helped to found a drama "national" in subject matter and free from pseudoclassical influence.

4. Poetry.—The attempt to Italianize Spanish poetry had failed through an overambitious intellectualizing of theme, on a basis of pedantic imitation, when language and metrics were still incapable of sustaining the burden. The Catalan Juan Boscán Almogáver (*c.* 1490–1542; see *Catalan Literature*, below), by reintroducing Italian metres (sonnet, *ottava rima, canzone*, tercet, blank verse), prepared the way for a much greater poet, his friend Garcilaso de la Vega (*c.* 1501–36), with whom the lyric was reborn. The importance of the new metres went much beyond form: in Garcilaso the most significant novelty is the verse paragraph of the *silva* (a free combination of 7- and 11-syllable lines), allowing a new concern with the analytical expression of thought and emotion. To a mastery of the poetic process derived from a study of Petrarch, Boccaccio, and Sannazzaro (and also of Theocritus, Virgil, Tibullus, and Horace), he added the gift of infusing an intense personal note into characteristic Renaissance themes. His meagre output of eclogues, elegies, and sonnets won him recognition for centuries as "the prince of Castilian poets" and largely determined the course of lyric poetry throughout the *siglo de oro*.

Fray Luis de León (1527–91), adopting chiefly Garcilaso's *lira* stanza (7, 11, 7, 7, 11) for poems charged with emotional sincerity, typified a so-called "Salamanca school," with its emphasis on content rather than form. Fernando de Herrera (1534–97) headed a contrasting school of Seville which, deriving equally from Garcilaso, was concerned rather with Petrarchan subtleties of refined sentiment; in a quartet of remarkable odes he gave vibrant expression to topical heroic themes. A movement of protest in defense of the short native metres, associated chiefly with Cristóbal de Castillejo (1490?–1550) was greatly reinforced by the printing of the *romanceros* after *c.* 1550, and by the evolving drama, which, while employing much metrical variety for specific effects, found in the octosyllable the accepted vehicle for narrative and description. Throughout the 17th century poets were to write in both the old and the new styles and metres, their practice still al-

lowing a notable degree of equation between the old styles and metres and "verse," and between the new and "poetry."

For epic poetry the metre was the *octava real* (*ottava rima*, *q.v.*), and the models Ariosto and Tasso, but the themes and heroes were those of overseas conquest and expansion, or defense of the empire and of the faith at home. Alonso de Ercilla y Zúñiga (1533–94) came nearest to achievement with his *La Araucana* (1569–90), telling at firsthand of native resistance to the conquest in Chile; its defects spring from a wavering concept of epic theory, now martial-heroic unrelieved, now amorous-fantastical with admixtures of prophecy and pedantry. Bernardo de Balbuena's *Bernardo* (1624), on a familiar medieval theme, and Lope de Vega's *Dragontea* (1598; a verse history of Sir Francis Drake's last voyage and death), and *Corona trágica* ("The Tragic Crown"; 1627; on Mary, Queen of Scots), may stand for the multitudinous activity in a literary kind that laid its compulsion on every poet of ambition.

5. Prose.—Prose before the Counter-Reformation produced some notable Lucianesque dialogues, especially from Alfonso de Valdés (the *Diálogos de Lactancio y un arcediano* and *de Mercurio y Carón* ["Dialogues Between Lactancio and an Archdeacon" and "Between Mercury and Charon"], 1528). His brother Juan wrote in Naples a *Diálogo de la lengua* (1535; published 1737) of high critical value. In style these stand at the other extreme from two of the works of Antonio de Guevara (1481?–1545), which enjoyed European notoriety as the Spanish counterpart of euphuism (*q.v.*): the *Reloj de príncipes* (1529) and the *Epístolas familiares* (1539–42). Both works were rendered into English by Elizabethan translators—the *Reloj* by Sir Thomas North and also by Lord Berners (*qq.v.*), the letters by Sir Geoffrey Fenton (*q.v.*). History in the tradition of Alfonso the Wise continued to be cultivated, patriotism waxing higher as Spain's imperial greatness casts its shadow over Europe; its last flowering was seen in the Latin *Historiae de rebus Hispaniae* (1592–1621) of Juan de Mariana (1536–1624), the translation of which into Spanish (*Historia general de España*, 1601) by the author himself marked the triumph of the vernacular for all literary purposes. Diego Hurtado de Mendoza (1503 or 1506–75) gave, in his *Guerra de Granada* (a history of the suppression of the Morisco rising of 1568–71; publ. 1627), an extreme example of the concern to write history upon the classical model; the *Anales de la corona de Aragón* ("Annals of the Crown of Aragon"; 1562–80) of Jerónimo de Zurita y Castro (1512–80) by contrast exalted serious documentation and impartiality over style.

But the landmarks in historical writing came from the New World, and showed the transmuting of vital experience into literature with a vividness unknown in Spain. The letters of Columbus and his accounts of his voyages, the *Cartas y relaciones al . . . Carlos V* ("Letters and Accounts to . . . Charles V") of Hernán Cortés, and many another narrative by humble *conquistadores* without literary artifice or pretension opened up new horizons to the reader and, as in the attempt to capture exotic landscapes in words, enlarged the resources of the language. Most engaging was the *Verdadera historia de la conquista de la Nueva España* ("True History of the Conquest of New Spain"), written in old age by Bernal Díaz del Castillo (*c.* 1492–*c.* 1581), who had a phenomenal memory, an infallible eye for the telling detail, and a passion for distributive justice. Bartolomé de las Casas (*q.v.*; 1474–1566), the "Apostle of the Indies," wrote history for noble yet partisan purposes: on his *Brevísima relación de la destrucción de las Indias* ("A Very Brief Account of the Destruction of the Indies"; criticizing Spanish colonial policy and the ill-treatment of the native population) rests a large measure of responsibility for the *leyenda negra* ("black legend") which Spain's enemies were for so long to use against it.

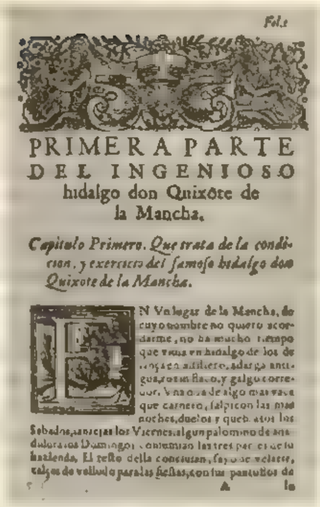
6. Mysticism.—The great period of Spanish mysticism coincided closely with the Counter-Reformation, though it had its antecedents. Ramon Llull had been a notable precursor in 13th-century Catalonia; and the *Dialoghi di amore* (published 1535; Eng. trans. *The Philosophy of Love*, 1937) of the expatriate Spanish Jew León Hebreo (Judah Abravenel; *c.* 1460–*c.* 1521), which, both in Italian and in Spanish translation, exercised a profound influence on 16th-century and later Spanish thought, allowed the infiltration of many Platonic images and doctrines. The literary importance of the mystics derives not only from their subject matter but also from the consideration that in the constant striving to transcend the limitations of language there were liberated previously untapped resources of expression, especially in the sphere of psychological probing. In the writings of St. Teresa of Ávila (1515–82), for example, *El libro de su vida* (her autobiography), *Las moradas, El castillo interior* (1588), and her letters, many of the gifts of a great novelist can be appreciated in embryo. Fray Luis de León, humanist and theologian, did not attain to the highest flights of the mystic ascent, but in his prose treatise *De los nombres de Cristo* (1583–85), as in his poems, he moves by his passionate devotion, his sincerity, and his profound feeling for nature, the whole finding expression in a style of singular purity. St. John of the Cross (1542–91) achieves preeminence by virtue of three poems expressing in exalted style and language the experience of Mystic Union.

7. The Novel.—Popular taste in the novel was dominated for a century by the monstrous progeny of the *Amadís de Gaula* (published 1508). These interminable romances kept alive certain ideals of medieval chivalry, but, having lost touch with life at every point, represented pure escapism, and in due course evoked, along with moral censure, various literary reactions. The pastoral novel was one (*see* PASTORAL). Akin to the eclogue naturalized from Italy by Garcilaso, it was modeled on the *Arcadia* (1504) of Jacopo Sannazzaro (1456–1530), and inspired by nostalgic echoes of an Arcadian Golden Age. Its shepherds were courtiers and poets who, no less than the knights-errant of chivalric romance, turned their backs on reality, with the purpose, however, of exploring more freely, against an idealized and carefree setting, the realm of the emotions. In Spain the first and best example was the *Diana* (1559?) of Jorge Montemayor (1520?–1561?); to the vogue it started, Cervantes with his *Galatea* (1584) and Lope de Vega with his *Arcadia* (1598) alike subscribed. In Gaspar Gil Polo's *La Diana enamorada* (1564), which was outstanding among the many sequels and imitations, the story became little more than a framework for a lyrical anthology.

A more positive reaction was seen in the picaresque novel (*q.v.*), initiated in 1554 with the brief, anonymous *Lazarillo de Tormes*. The word *pícaro*, of doubtful origin, does not appear in this text; the kind, native to Spain, was to exert influence in many foreign literatures. The *pícaro* was essentially the antihero, innocent of ideals and concerned only to keep alive, who lived by his wits, and, as he passed from master to master, saw and depicted life from underneath. Important for its part in guiding fiction back to direct observation of life, the picaresque formula had little to contribute to the development of the novel as an art form. The seed sown by *Lazarillo* did not bear fruit for nearly 50 years; and with the *Guzmán de Alfarache* (1599–1604) of Mateo Alemán (1547–1614?), whose interminable moralizings showed at its heaviest the Counter-Reformation's influence on literature; and Quevedo's *La vida del buscón* ("A Scoundrel's Life"; 1626), in which realism has become a cynically grotesque caricature of human values, the picaresque kind, though it continued abundant throughout the 17th century, may be held to have given what it had in it to give.

Cervantes (Miguel de Cervantes Saavedra, *q.v.*; 1547–1616), the culminating figure in his country's literature, produced in *Don Quixote* (part 1, 1605; part 2, 1615) what may be taken to be the prototype of the modern Spanish novel. Nominally a satire on the already moribund romances of chivalry (*see* ROMANCE), the conception allowed of the presentation of reality on two levels: the "poetic truth" of Don Quixote and the "historic truth" of his squire, Sancho Panza. In pursuing the constant interaction of these equally valid but rarely compatible attitudes to life, Cervantes revealed the novel's scope as a philosophical commentary on existence; and in tracing the constant interplay of character between master and squire—in contrast with the static characterization of previous fiction—he established psychology as one of the touchstones of its excellence. In the *Novelas ejemplares* ("Exemplary Novels"; 1613) Cervantes particularized

EL INGENIOSO
HIDALGO DON QVIXOTE DE LA MANCHA,
Compuesto por Miguel de Ceruantes Saauedra.
DIRIGIDO AL DVQVE DE BEIAR, Marques de Gibraleon, Conde de Benalcaçar, y Bañares, Vizconde de la Puebla de Alcozer, Señor de las villas de Capilla, Curiel, y Burguillos.
Año, 1605.
CON PRIVILEGIO,
EN MADRID, Por Iuan de la Cuesta.



Fol. 1
PRIMERA PARTE
DEL INGENIOSO
hidalgo don Quixote de la Mancha.
Capitulo Primero. Que trata de la condicion, y exercicio del famoso hidalgo don Quixote de la Mancha.

BY COURTESY OF THE TRUSTEES OF THE BRITISH MUSEUM; PHOTOGRAPH BY J. R. FREEMAN AND CO

TITLE PAGE (LEFT) AND FIRST PAGE OF TEXT FROM THE FIRST EDITION (1605) OF "DON QUIXOTE" BY CERVANTES

his claim to be the first to write *novelas* (short stories in the Italian manner) in Spanish by differentiating between those which interest by the action and those of which the merit lies in the mode of telling, "making something out of nothing."

8. Later Drama.—The *comedia* (*i.e.*, the drama) achieved its formula and its splendour in the genius of Lope de Vega (1562–1635), to fill thereafter with an incredible fertility of invention the 100 years before the death of Calderón in 1681. Its manual was Lope's own poetic treatise, *El arte nuevo de hacer comedias en este tiempo* ("The New Art of Making Dramas in This Time"; 1609), which firmly rejected the classical and neoclassical "rules," opted for a blend of comedy and tragedy (*comedia* is in Spanish an all-embracing term for drama) and for metrical variety, and made of the *vulgo* (*i.e.*, public opinion) the ultimate arbiter of taste.

The *comedia* was essentially, therefore, a "social" drama, ringing a thousand changes on the accepted foundations of society: respect for crown, for church, and for the human personality, the latter being symbolized in the *pundonor* ("point of honour") that Lope commended as the best theme of all "since there are none but are strongly moved thereby." This *pundonor* was a matter largely of convention, "honour" being equivalent, in a very limited and brittle sense, to reputation. Here too the drama was social; characters, to merit esteem, had perforce to abide by the prescriptions of their fellows. It followed that this was a drama less of character than of action and intrigue, which rarely, if ever, grasped the true essence of tragedy (*q.v.*) or knew the cathartic function. What the great Spanish playwrights did possess was a remarkable sense of stagecraft and the ability to make the most intricate plot grip to the end, however arbitrary the final tying or untying of the knots.

Lope, the "prodigy of nature," as Cervantes called him, who claimed authorship of 1,800 *comedias*, and more than 400 *autos sacramentales* (of which about 500 of plays and *autos* together are extant), swept public and fellow-dramatists alike into vassalage by his powers of creation. Little that he wrote was perfect, but he had an unerring sense for the theme and detail that could move an audience conscious of being on the crest of its country's greatness to respond to a mirroring on the stage of some of the basic ingredients of this greatness. Because of him the *comedia* became a vast sounding board for every chord in the Spaniard's consciousness, a "national" drama in the truest sense. His plays have been classified into religious, mythological, pastoral, and novelesque, etc. In reality only two of these groups really matter: the native historical, and the *capa y espada* ("cloak-and-sword") plays of contemporary manners. Lope ransacked medieval chronicle, the *romancero*, and popular legend and song for heroic themes, chosen for the most part as throwing into relief some aspect of the national character, or of that social solidarity on which contemporary Spain rested. Among the best are *Fuente Ovejuna*, *Peribáñez y el comendador de Ocaña*, *El Caballero de Olmedo*, and *La estrella de Sevilla*. (There is some doubt about the authorship of the last-named play.) (For translations, see *Five Plays of Lope de Vega*, 1961.)

The "cloak-and-sword" play, a type which weighed more and more in the *comedia* after Lope, was pure diversion, written to a number of hollow conventions, with much disguising, mistaking of identities, duelling, falling in and out of love and false alarms about "honour," and a duplicating of the plot below stairs between *gracioso* (the gallant's humorous or would-be humorous lackey) and lady's maid. Though contemporary, it could in no sense be held to give a true picture of society, but it gave pleasure by its infinite resource and dexterity, its sparkling dialogue, its tripping convolutions in the relations between the sexes, and its constant implied paean to the enjoyment of the pleasures of the moment in an irresponsible world. The essentially lyrical character of much of the *comedia* further explains its charm.

The greatest of Lope's immediate successors was Tirso de Molina (*c.* 1584–1648), whose *El burlador de Sevilla* (1630; Eng. trans., *The Trickster of Seville*, in *The Classic Theatre*, volume three [1958] edited by Eric Bentley) presented the Don Juan legend on the stage for the first time (*see* also DON JUAN). His *Prudencia en la mujer* ("Prudence in a Woman"; 1634) figures among the greatest of Spanish historical dramas, as does *El condenado por desconfiado* (1635; Eng. trans., *The Doubted Damned*, 1956) among theological, while his "cloak-and-sword" comedies include some of the liveliest of the kind. Juan Ruiz de Alarcón y Mendoza (*c.* 1581–1639) struck a distinctive note which some have sought to relate to his Mexican birth and upbringing, others to his spinal deformity. His 20 plays were sober, studied, and imbued with serious moral purpose; *La verdad sospechosa* ("Truth Suspected"; 1634) inspired Corneille's *Le menteur*. The dramatic conflict between love and honour posed in *Las mocedades del Cid* (1599?), by Guillén de Castro y Bellvís (1569–1631), was similarly the source of Corneille's *Le Cid*. But moral purpose and dramatic conflict are infrequently found among the plays of Antonio Mira de Amescua (1574?–1644), Luis Vélez de Guevara (1579–1644), Juan Pérez de Montalbán (1602–38), and the many others who, with more or less distinction, if with dwindling originality, bridged the transition from Lope to Calderón.

9. Culteranismo and Conceptismo.—In poetry and prose the early 17th century was marked by the rise and spread of two interrelated movements. That known as *culteranismo*, of which Luis de Góngora y Argote (1561–1627) was archpriest, resumed, as one of its facets, earlier attempts to ennoble the language by re-latinizing it. In Góngora's *Polifemo y Galatea* (1612) and *Soledades* (1613–17; Eng. trans., 1931), this process was not only carried to extremes in vocabulary, syntax, and word order, so that the reader must needs be something of a latinist, but expression was garbed in the full panoply of classical myth and allusion, and further complicated by every subtlety of which metaphor is susceptible. Yet this poetry was something other than a deliberate cult of obscurity. Theme and treatment make clear the attempt to achieve a poetry not merely "pure" but timeless, to write poems which, rediscovered after the lapse of hundreds or thousands of years, could be acclaimed still fresh and immortal. Indeed, after 300 years Góngora was so rediscovered; but in his own age his example invited many who lacked his genius to slavishly imitate his procedures.

The twin affectation, *conceptismo*, played on ideas as *culteranismo* did on language. The *conceptista* purveyed thought, and sought to shock the reader into attention by both the subtlety and the violence of his conceits. Aiming always at the semblance of profundity, the quintessential, his style was concise and epigrammatic, and demanded for comprehension not the well-stocked mind but one infinitely nimble and alert. *Conceptismo* thus belonged properly to prose, inclined to satire, since it was much concerned with stripping off appearances, and found its most adequate outlet in the essay. Francisco Gómez de Quevedo y Villegas, (1580–1645), the master satirist of his age in the literary, the political, and the social sphere, and one of Spain's greatest wielders of language, was, in Los Sueños (1627), its outstanding exponent.

Baltasar Gracián y Morales (1601–58), its preceptist, reduced all its refinements to an exact code in his *Agudeza y arte de ingenio* (1648), as he also sought to codify in a series of treatises the art of worldly living (*El héroe*, 1637; *El discreto*, 1646; *El oráculo manual y arte de prudencia*, 1647). Gracián, if only doubtfully a philosopher, was certainly a thinker, and his allegorical novel *El criticón* (1651–57), a pessimistic interpretation of life as a "daily dying," was to influence La Rochefoucauld, Schopenhauer, and Nietzsche.

10. Calderón.—Pedro Calderón de la Barca (1600–81) spanned the century of Spain's decline, and his drama constitutes a studied expounding of patterns of behaviour (the *pundonor*) or belief. He wrote 80 *autos sacramentales* and these, with *La vida es sueño* (*Life Is a Dream;* several English translations), *La devoción de la cruz* (Eng. trans. by F. Honig, *Devotion to the Cross*, in *Four Plays*, 1961), and *El mágico prodigioso* ("The Marvelous Magician"), which give what dramatic tension is possible to a highly intellectualized exposition of Catholic dogma, make him the perfect literary representative of the Counter-Reformation. In the so-called honour plays—*El médico de su honra* (Eng. trans. by Roy Campbell, *The Surgeon of His Honour*, 1960), *A secreto agravio secreta venganza* (*Secret Vengeance for Secret Insult*, in Honig's translation mentioned above), *El pintor de su deshonra* ("The Painter of His Dishonour"), and *El mayor monstruo los celos* ("The Greatest Monster, Jealousy")—the cold logic with which an unreal code is pursued to the extreme becomes repugnant. *El alcalde de Zalamea* (*The Mayor of Zalamea*, Honig's translation), a reworking of a play by Lope, is perhaps his most successful play on the human level. *La vida es sueño*, to the extent that it raises profound philosophical issues on a plane of universality, has given him great fame abroad.

Francisco de Rojas Zorrilla (1607–48; *Del rey abajo, ninguno*, 1650), and Agustín de Moreto y Cabaña (1618–69; *El desdén con el desdén*, 1654) stand out among those who revolved in Calderón's orbit. After Calderón's death Spanish drama lay dead for a hundred years. *Culteranismo* and *conceptismo*, though symptoms rather than causes of decline, had played their part in the stifling of imaginative literature, and by the close of the century nothing but the shell remained of the greatness that had been the *siglo de oro*.

C. The 18th Century

With the advent of the Bourbon dynasty in 1700, and its establishment after the War of the Spanish Succession (1701–13), a profound renewal of the country's intellectual life took place. Numerous academies were created, the most influential being the Real Academia de la Lengua Española, founded in 1713 to maintain the purity of the language (*Diccionario de autoridades*, 1726–39; *Gramática*, 1771). Men of letters again went to school abroad, and discovered how far Spain had deviated from the intellectual courses of Western Europe.

Moreover, a new spirit of inquiry into the national heritage was to carry back to Luis de León, to Herrera, and to Garcilaso an awareness that in the early decades of the century had seemed limited to Góngora, Quevedo, and Calderón (worst of models for an imitative generation), and was indeed to go back earlier still, to unearth the forgotten medieval literature. Gregorio Mayáns y Siscar (1699–1781), librarian at the royal library in the 1730s, edited Juan Luis Vives (in Latin), Juan de Valdés, and Luis de León, and, in his *Vida de Cervantes* (1737), initiated Cervantine criticism. The Augustinian church historian Enrique Flórez (1702–73), embarking on the vast *Teatro geográfico-histórico de la iglesia de España* (better known as *España sagrada*, 29 volumes, 1747–55; continued by others), helped resurrect the whole cultural background of medieval Christian Spain. A landmark of even greater importance was the publication, in Tomás Antonio Sánchez's *Poesías castellanas anteriores al siglo XV* (1776–90), of the *Poema de mío Cid*, the works of Gonzalo de Berceo, the *Libro de Alexandre*, and Juan Ruiz's *Libro de buen amor*. From all this critical activity there resulted a debate between old and new that, waged throughout the middle decades of the century, compelled both sides to reason their positions and marked the birth of a new critical approach to literature.

Two names stand out: Ignacio de Luzán Claramunt (1702–54), educated in Italy and well-grounded in foreign literatures, whose work on poetics (1737) introduced to Spanish readers the aesthetic of Muratori, Boileau, and Le Bossu, and launched the great neoclassical polemic in Spain; and Benito Jerónimo Feijoo y Montenegro (1676–1764), a Benedictine whose *Teatro crítico universal* (8 volumes, 1726–39) and *Cartas eruditas y curiosas* (15 volumes, 1742–60) comprised more than 280 essays ranging over the whole of human knowledge. Assailing error, prejudice, and superstition wherever he found them, and so bitterly assailed in his turn that the king intervened to protect him, Feijoo made a monumental contribution to the intellectual emancipation of Spain. Imaginative prose produced the *Noches lúgubres* (publ. 1789–90) of José de Cadalso y Vázquez (1741–82), looking forward to Romanticism; and the *Fray Gerundio . . .* (1758) of José Francisco de Isla (1703–81), a satire, in the guise of biographical fiction, on affectation in the pulpit, which looked back to the picaresque novel.

Poetry, moribund for nearly 100 years, raised a timid head in a small group at Salamanca, led by the Augustinian poet and orator Diego González (1731–94), which toward 1775 turned for inspiration to Luis de León, just as two decades later a group at Seville sought to revive the glories of Herrera; and again (as in the 16th century), though the lines were now more blurred, Salamanca stood for content, Seville for form. Juan Meléndez Valdés (1754–1817), who learned to think from John Locke and to feel from Edward Young, best exemplifies the combination of new influences at work. A conscious artificer rather than a great poet—though the nearest to one among the Salamancans—he helped poetry through the painful apprenticeship necessary to its rehabilitation.

For drama, the second half of the century saw the great battle of the neoclassical "rules" (meaning chiefly the unities of place, time, and action) that the *siglo de oro* had spurned. *La Raquel* (1778) of Vicente Antonio García de la Huerta y Muñoz (1734–87), combining a traditional Spanish theme with neoclassic construction, showed the capabilities of the reformist school. His vast compilation of earlier drama, the *Theatro Hespañol* (16 volumes, 1785–86), made apparent by its omission of Lope, Tirso, and Alarcón how unsubstantial were the grounds on which condemnation of the early drama rested.

It fell to Ramón de La Cruz (1731–94) to bridge the gap, unwittingly but effectively, by his resurrection on a somewhat ampler scale of the earlier *paso* (one-act prose skit) or longer *entremes* of Lope de Rueda, Cervantes, and Luis Quiñones de Benavente (*c.* 1589–1651). Based on acute satirical, though in the main good-humoured, observation of the Madrid scene, his one-act *sainetes* ("sketches") could not, because of their brevity, transgress the unities or offend the purist; at the same time they delighted the *vulgo* and brought the drama back from pseudoantiquity to the function of commenting on life and society. Leandro Fernández de Moratín (1760–1828) applied the lesson to the full-length play, and produced comedies imbued with deep social seriousness which, written to a meticulous observance of the unities, were yet good theatre (*El viejo y la niña* ["The Old Man and the Girl"], *La comedia nueva* ["The New Comedy"], *El sí de las niñas* [Eng. trans., *When a Girl Says Yes*, in *Spanish Drama*, edited by Angel Flores, 1962]. *La comedia nueva*, a remorseless flaying of such writers as Luciano Francisco Comella y Villamitjana (1751–1812), who had reduced to absurdity what they fondly believed to be the Calderón tradition, absolves one from any need to read their work. Moratín's dialogue in this play ranks among the best prose of the 18th century.

D. The 19th Century

1. Romanticism.—The first third of the 19th century proved but a prolongation of the 18th, the Napoleonic Wars and their long aftermath casting a blight on letters. The inspiriting odes of a Juan Nicasio Gallego (1777–1853), or a Manuel José Quintana (1772–1857), or the impassioned prose of a Gaspar Melchor de Jovellanos (1744–1811), show neoclassic objectivity and proportion set aflame with the emotion of outraged patriotism. War

against France did not mean repudiation of French literary influences. Most of the thousands of liberals driven into exile by Ferdinand VII after 1823 sought refuge in France. Having drunk there the heady wine of Romanticism, they flocked back to Spain on Ferdinand's death in 1833, a date often taken as marking the beginning of the Romantic movement in Spain.

Such fortuitous contacts were far from being the sole source of Spanish Romanticism. The ground for it had been prepared in Cádiz from 1814 onward in a notable debate on literary values initiated by the German Johann Niklaus Böhl von Faber; in Barcelona with the founding in 1823 of the review *El Europeo* ("The European"), edited by a Catalan, an Englishman, and an Italian; and in Madrid with Agustín Durán's critical essay on the drama of the *siglo de oro* (1828), and with his vast *Colección de romances antiguos* ("Collection of Ancient Ballads"; 1828–32). Romanticism in France, moreover, was largely a revolt against native literary tradition and a turning abroad, notably to Spain, for new sources of inspiration; in Spain it implied the rejection of an alien neoclassicism and to that extent a return to the spirit of its own earlier classics. All the formal characteristics of Spanish Romantic drama—the mingling of kinds, the rejection of the unities, metrical variety (now extended to include prose)—had characterized the drama of Lope and his contemporaries, who had, moreover, treated many of its themes (taken, by choice, from the Spanish Middle Ages).

It is from a study of these themes that the novelty and significance of the new school becomes apparent. Whereas the drama of the *siglo de oro* had rested on social solidarity, Romantic drama was in revolt against society: its protagonist staked everything on his right to be himself, *especie única,* and, deliberately flouting convention, defied society to stand in his way. In France, tragedy was by Romanticism deflected into drama; in Spain, drama into tragedy.

The Romantic movement in Spain, coming to fruition a generation later than elsewhere, knew a correspondingly short and checkered life. The six plays that epitomize its dramatic achievement fall between 1834–44: *La conjuración de Venecia* ("The Venetian Conspiracy"), by Francisco de Paula Martínez de la Rosa (1787–1862); *Macías,* by Mariano José de Larra (1809–37); *Don Álvaro o la fuerza del sino* ("Don Alvaro, or the Force of Destiny"), by Ángel de Saavedra, duque de Rivas (1791–1865); *El trovador,* by Antonio Garcia Gutíerrez (1813–84); *Los amantes de Teruel,* by Juan Eugenio Hartzenbusch (1806–80); and *Don Juan Tenorio,* by José Zorilla y Moral (1817–93). (The poetry of José de Espronceda [1808–42] also belongs to this period). Of these six plays, *Don Álvaro* came nearest, in the theatre, to expressing a "philosophy" of Romanticism; and the preface, by the critic and orator Antonio Alcalá Galiano (1789–1865), to Rivas' narrative poem, *El Moro expósito* ("The Abandoned Moor"; 1834) came nearest to supplying a foundation of precept. But the movement never possessed the consistency of a school, a leader, or a corpus of doctrine. Espronceda was the one Romantic who lived his Romanticism, if with an element of Byronic posturing; his *Estudiante de Salamanca, Canciones,* and the unfinished *El diablo mundo* ("The Devilish World") were the only subjective lyricism of value that the period produced, and marked, too, a milestone in the enlargement of poetic form. In comparison, the *Romances históricos* (1841) of Rivas, and the *Cantos del trovador* ("Troubadour Songs"; 1840–41) of Zorrilla were little more than exercises, brilliant within the limitations of their kind, in the retelling of picturesque legend.

2. Costumbrismo.—Side by side with, and beginning a little earlier than, Romanticism flourished a movement called *costumbrismo*—a kind of realistic prose writing, often within a narrative framework, having affinities with the De Coverley papers of Joseph Addison and Richard Steele, and particularly suited to the Spanish genius. Its chief vehicles are the *cuadro de costumbres* and the *artículo de costumbres*—short literary sketches, describing customs, manners, or character, the *cuadro* inclining to description for its own sake, the *artículo* being more critical and satirical, and both generally concentrating on a particular locality or region.

The forerunners of the movement were Santos López Pelegrín (1801–46) and Sebastian de Miñano (1779–1845) whose *Cartas de un pobrecito holgazán* ("Letters from a Poor Idler"; 1820), attacking the monarchy and satirizing Spanish customs and politics, is sometimes regarded as the first *costumbrista* work. The three most important *costumbristas* were Larra, the outstanding prose writer and critical mind of his age, who dissected society pitilessly in his *artículos,* collected in 1835–37; Ramón de Mesonero Romanos (1803–82), whose *Escenas matritenses* ("Scenes of Madrid"; 1836–42) give a vivid picture of the social life of the period, especially in Madrid; and Serafín Estébanez Calderón (1799–1867), whose *Escenas andaluzas* ("Andalusian Scenes"; 1847) portray the manners, folklore, and history of Andalusia. These, and other *costumbrista* writings, helped to prepare for the revival of the novel.

3. Post-Romantic Poetry.—Three poets bestride the third quarter of the century and, in their diversity, reveal how one of Romanticism's major services was its liberation of the individual personality. Gustavo Adolfo Bécquer (1836–70), accounted a Romantic, was concerned only to give expression to his own tortured emotions. His 76 brief *Rimas,* which owe something to Heine, bear the stamp of a deeply moving sincerity. In his *Leyendas* ("Legends") Bécquer proved himself also a prose stylist in a richly poetic and imaginative vein. Ramón de Campoamor y Campoosorio (1817–1901) affected the epigrammatic in his *Doloras, Pequeños poemas,* and *Humoradas* (new poetic forms of his own invention), making a sustained attempt at originality and at bringing poetry back into the realm of ideas. Gaspar Núñez de Arce (1832–1903) likewise endowed poetry with a purpose, the social purpose of stimulating the civic virtues and defending the body politic against dangerous heresies. His *Gritos del combate* ("Combat Cries"; 1875) represented a noble if despairing attempt, at times too declamatory, to stem the tide of the abuse of democracy. Among somewhat later poets were Salvador Rueda (1857–1933), an exuberant local colourist who has been regarded as a precursor of Modernism; José María Gabriel y Galán (1870–1905), whose works extoll the traditional virtues of the Castilian countryside; and Rosalía de Castro (1837–85), a true poet of Galicia (*see* also below), whose one volume of poems in Castilian, *En las orillas del Sar* (1884), invites comparison with Bécquer.

4. The Novel.—The last-named poets, each identified with his *patria chica* (native region), shared with the novelists a quality that was to characterize Spanish fiction on its rebirth. For more than two centuries, the kind in which Spain had made its most striking contribution to world literature—the novel—had been virtually extinct. Its place had been taken during the Romantic period by the *cuadro de costumbres,* and, although attempts had been made by Larra, Rivas, Espronceda, and others to write historical novels in the manner of Sir Walter Scott, this kind of fiction never took root in Spain. Indeed, the novel, on its revival, was both an extension of the realistic and regional elements of *costumbrismo,* and a continuation of the tendencies of earlier Spanish novelists. The first novels of the revival were more interesting for their powers of observation and description than for imaginative or narrative quality.

It was Fernán Caballero (1796–1877), who, in 1849, with *La gaviota* (*The Sea Gull*), determined the particular technique of observation that was to rehabilitate the novel. This simple tale of romantic disillusion captivated less by its plot than by its Andalusian setting and vividness of colour and detail. In 1874, coinciding with the restoration of the Bourbon monarchy, the great period of the regional novel began, for, in this year Pedro Antonio de Alarcón (1833–91), a waverer between the esoteric-romantic and the pedagogic, achieved his masterpiece in *El sombrero de tres picos* (*The Three-Cornered Hat*), a sparkling tale of Andalusian peasant malice. A fellow-Andalusian, Juan Valera y Alcalá Galiano (1824–1905), brought psychological insight and a classical note of cultured detachment to four novels which depended less on local realism, acutely observed though this was, than on knowledge of men and women: *Pepita Jiménez* (1874), *Las ilusiones del doctor Faustino* (1875), *El comendador Mendoza* (1877), and *Doña Luz* (1879). José María de Pereda (1833–

1906), graduating through a long series of sketches on life in the mountains of his native Santander, emerged as the greatest of the regional writers; his realism was no longer merely picturesque but a powerful re-creation of nature as the abiding reality, more important than the individual and therefore than the plot. *Sotileza* ("Subtlety"; 1884) and *Peñas arriba* ("Up the Mountains"; 1893), perhaps his best novels, revealed him as a champion too of traditional values—religion, the family, country life—in a dissolving society typified by the big city.

Emilia Pardo Bazán (1851–1921) attempted, in two novels of Galicia, *Los Pazos de Ulloa* (1886) and *La madre naturaleza* ("Mother Nature"; 1887), to combine the Spanish Christian outlook with French Naturalism, which she had already examined curiously and with many reserves in the essays in *La cuestión palpitante* ("The Crucial Issue"; 1882–83). The attempt made clear their incompatibility, and in later novels her return to a genuinely Spanish realism, in which spiritual values also found their place, was complete. Armando Palacio Valdés (1853–1938) was the novelist of Asturias even when the stage was transferred to Andalusia, as in the perennially popular *La hermana San Sulpicio* (1889; Eng. trans., *Sister Saint Sulpice,* 1890), or to Valencia, as in *La algería del capitán Ribot* (1899; Eng. trans., *The Joy of Captain Ribot,* 1900). He also experimented, somewhat halfheartedly, with Naturalism, in *La espuma* (1890; Eng. trans., *The Froth,* 1891) and *La Fe* (1892; Eng. trans., *The Faith,* 1892), but was saved by his most engaging quality, humor.

Besides this cult of regionalism, the fecundity in the novel of Benito Pérez Galdós (1843–1920) created a world in itself. Going to Madrid from the Canary Islands in 1862, Pérez Galdós was better able than the regional writers to see Spain in the round; and, after living through one of the most turbulent chapters in Spanish history, he addressed himself to imaginatively re-creating its antecedents, beginning with the war against Napoleon. The five series, containing 46 novels of his *Episodios nacionales* ("National Episodes"; 1873–79 and 1898–1912), embraced 70 years of the country's history, from Trafalgar to the early years of Alfonso XII, and taught generations of Spaniards much of what history they knew. His other series (the *Novelas de la primera época* and the *Novelas españolas contemporáneas,* in which he treats contemporary society) completed the revelation of Spain to Spaniards; embodying the author's liberal and challenging views, they constituted a concerted campaign to regenerate and Europeanize Spanish society and thought.

5. Drama.—The drama, disorientated after the brief Romantic efflorescence, produced few outstanding works and no clear conception of goal or function. Manuel Tamayo y Baus (1829–98), who began by oscillating between and even attempting to fuse classical tragedy and Romantic drama, gradually evolved from verse to prose and from the historical-heroic to the contemporary-social; he achieved fame by the isolated *Un drama nuevo* (1867; Eng. trans., *A New Drama,* 1915), a powerful portrayal, in which the characters are members of Shakespeare's company of actors (including Shakespeare himself). The hero is the clown, Yorick, who is compelled to act on the stage his personal tragedy of betrayal by his wife, and retributive murder. Adelardo López de Ayala (1829–79) used considerable technical gifts to pillory bourgeois vices, in, for example, *El tejado de vidrio* ("The Glass Roof"; 1856), and *Consuelo* (1870). The Nobel Prize for Literature (1904) set a seal on José Echegaray y Eizaguirre (1832–1916), whose 63 plays fall into two main groups. In the first, imbued with a violent neo-Romanticism, drama becomes melodrama with a constant striving after effect and a basic falsity of character, passion, and situation alike. The second comprises a serious, often tragic, drama of social problems in which Ibsen can be seen as one of several foreign influences though here, too, passions were apt to be torn to shreds and denouements to rely on violent dispatch: *El gran Galeoto* (1881; Eng. trans., *The Great Galeoto,* 1922), *O locura o santidad* (1877; Eng. trans., *Madman or Saint,* 1907), *El hijo de don Juan* ("Don Juan's Son"; 1892). Joaquín Dicenta (1863–1917) brought the drama nearer to earth with an unpleasantly realistic study of working-class conditions in *Juan José* (1895). Failure to master the problems involved in the change from the novel to drama robbed Pérez Galdós of full success in the theatre, to which he turned increasingly in his concern to stimulate the social conscience: *Realidad* ("Reality"; 1892); *La loca de la casa* ("The Madwoman in the House"; 1893); *Electra* (1901).

6. The Generation of 1898.—Once again, as in 1700, the turn of the century brought about a radical change in literary values and directions. For two decades and more a mood of scathing analysis had been developing with the growing conviction that behind the peace and order of a nominally representative regime much rottenness lay concealed. Pérez Galdós sensed and gave voice to the disquiet; and it evoked, in Ángel Ganivet's *Idearium español* (1897), one of the most searching analyses of the Spanish character ever written. With 1898 came the Spanish-American War, which left Spain stripped of the last vestiges of its trans-Atlantic and Pacific empire. The imperial cycle begun in 1492 had ended in ignominy, and thinking Spaniards embarked on an analysis of their country's ills, a scrutiny of its possible destiny, and an attempt to shock the national mentality out of its *aboulia* (or lack of will). Among literary consequences were the informing of the novel with a new seriousness of purpose, and the emergence of the essay—critical, psychological, philosophical—to a new importance. Novelists and essayists constitute what Azorín first called the "generation of '98." Rarely in agreement in their diagnosis or on the treatment proposed for the patient, they reinvigorated Spanish letters to a point where these again commanded respect abroad and, as part of the process, they laid Spain open to English, French, German, Russian, and other influences on a scale never known before.

Miguel de Unamuno (1864–1936) dominated the literary scene for a generation. In him the national problem was intertwined with his obsession with the personal problem of immortality. The former he studied acutely in the five essays in *En torno al casticismo* ("On Spanish Purism"; written 1895, publ. 1902), and in the *Vida de Don Quijote y Sancho* (1905; Eng. trans., *Life of Don Quixote and Sancho,* 1927), an analysis in depth of Cervantes' characters. The problem of immortality was examined in his most important work, *Del sentimiento trágico de la vida* (1913; Eng. trans., *The Tragic Sense of Life in Men and in Peoples,* 1921). A deliberately provocative rather than a systematic thinker, he aimed at sowing spiritual disquiet. The novel was to him an extension of the essay, as the theatre was of the novel, a medium for discussion of the fundamentals of personality, hence stripped of externals and as timeless as the *Soledades* of Góngora; representative examples of his fiction are *Niebla* (1914), *Abel Sánchez* (1917), and *Tres novelas ejemplares y un prologo* (1921).

Azorín (José Martínez Ruiz; 1874–1967) concerned himself with the reinterpretation of earlier literary values and of the Spanish countryside, in, for example, *El alma castellana* ("The Castilian Soul"; 1900), *La ruta de Don Quijote* ("Don Quixote's Route"; 1905), and *Clásicos y modernos* ("Classics and Moderns"; 1913). An artist in criticism and a miniaturist of fine sensitivity, he contributed powerfully to the deflation of the hollow rhetoric that had vitiated much 19th-century writing. José Ortega y Gasset (1883–1955) brought to the analysis of the national consciousness a mind formed in Germany in the study of neo-Kantian thought. From criticism and psychology (*Meditaciones del Quijote,* 1914 [Eng. trans., *Meditations on Quixote,* 1961]; *El espectador* ["The Spectator"], 1916–34) he passed to national problems (*España invertebrada,* 1921; Eng. trans., *Invertebrate Spain,* 1937) then to international (*El tema de nuestro tiempo,* 1923 [Eng. trans. *The Modern Theme,* 1933, 1961]; *La rebelión de las masas,* 1929 [Eng. trans. *The Revolt of the Masses,* 1932]). His *Revista de Occidente* ("Magazine of the West"; 1923–36), directed to keeping Spain abreast of contemporary foreign thought, proved a major intellectual force.

Pío Baroja (1872–1956) repudiated tradition, religion, and the cult of the individual, and sought to be an arch-European, fixing his gaze on the future and making a cult of social action. His *Memorias de un hombre de acción* ("Memories of a Man of Action"; a cycle of 22 novels set in the early 19th century) are thus less characteristic than his 11 trilogies on the contemporary scene

—*La raza* ("The Race"; 1908–11); *La lucha por la vida* (1904; Eng. trans., *The Struggle for Life*, 1922–24); *Agonías de nuestro tiempo* ("Agonies of Our Time"; 1926), etc. Insensitive to art for art's sake, Baroja often depresses through his concern to arouse discontent with material conditions; but his novels, full of rude vigour and a fierce independence of spirit, are seedbeds of ideas. There was rude vigour too, with richness of colour and greater narrative skill, in Vicente Blasco Ibáñez (1867–1928), a regional novelist in, for example, *Flor de Mayo* (1895; Eng. trans., *Mayflower*, 1921) and *La barraca* (1898; Eng. trans., *The Cabin*, 1917), on his native Valencia, who wrote also on contemporary social problems from the standpoint less of the generation of '98 than of the anarchist—for example, *La bodega* (1906) and *La horda* (1905). Blasco Ibáñez won international renown with novels of World War I; the most famous was *Los cuatro jinetes del Apocalipsis* (1916; Eng. trans., *The Four Horsemen of the Apocalypse*, 1918). Ricardo León (1877–1943) was a conscious stylist who sought to recapture the traditional Christian values of a society threatened with materialism (*Casta de hidalgos*, 1908; *Alcalá de los Zegríes*, 1909; *El amor de los amores*, 1910). His work, however, belongs less in outlook and style to the generation of '98 than to the 20th century.

E. The 20th Century

Critics and literary historians differ about the dividing line between the generation of '98 and the so-called *Novecentista*, which by some is taken to mean the generation immediately following that of '98, and by others is extended to cover the whole of the period from 1900 to the 1930s. In general, however, the term is applied to the writers of the early 20th century who sought to renew intellectual and aesthetic standards after the passionate involvement of their immediate predecessors.

1. The Novel.—In Ramón Pérez de Ayala (1880–1962) the novel is at once a satisfying art form and a forum for philosophical discussion tinged with Asturian humour. *Troteras y danzaderas* (1913) recaptures something of the vein of Juan Ruiz. *Belarmino y Apolonio* (1921), a projection of the old debate between faith and reason, makes its characters almost symbolic, as do *Tigre Juan* and its continuation *El curandero de su honra* (1926; Eng. trans., *Tiger Juan*, 1933) on the traditional theme of honour. Gabriel Miró (1879–1930) was a lyric poet in prose, with gifts of description and evocation (shown in *Figuras de la pasión del Señor* ["Scenes of the Passion of Our Lord"], 1916–17; *Años y leguas* ["Years and Leagues"], 1928) which retard the action of his novels but have given him the reputation of a supreme artist in words. In these writers can be seen qualities and tendencies to some extent incompatible with the basic art of the novel. This as a literary kind fell under the influence of Ortega y Gasset, who, in *La deshumanización del arte* (1925; Eng. trans., *The Dehumanization of Art*, 1956), propounds the principles of a pure, depersonalized art. With it, he published notes on the novel, predicting its decline. In the following decade Benjamín Jarnés (1888–1950) and others attempted, without complete success, to apply a technique of pure art to the novel; Jarnés' works are the outstanding examples of the Surrealist novel in Spain.

The publication in 1929 of *Imán*, based on experience of military service in Morocco, by Ramón José Sender (1902–), marked a return to realism and social criticism. Like his later novels (the trilogy *Los terminos del presagio* ["The Terms of the Omen"], 1931–34; *El epitalamio del prieto Trinidad*, 1942; etc.), written in Spain, Mexico, and the United States, where he settled in 1942, it is concerned with the human situation in all its horror, and with the search for a satisfying philosophical and ethical system. (An English translation of *Imán* appeared in 1935, entitled in the United States *Pro Patria* and in Great Britain *Earmarked for Hell*. A number of his other novels are available in English translations.)

Sender was followed by Max Aub (1903– ; *El laberinto mágico* ["The Magic Labyrinth"], 1943–45), and Arturo Barea (1897–1957), whose autobiographical trilogy of novels was first published in England (where he settled after the Spanish Civil War) with the title *The Forging of a Rebel* (1947), and had great influence on writers there and elsewhere in Europe. It was published in Spanish in 1951–52 as *La forja de un rebelde*. Novelists of promise to emerge after the Civil War were Camilo José Cela (1916–); Carmen Laforet (1921–); Juan Antonio de Zunzunegui (1901–); and José María Gironella (1917–).

2. Drama.—With the new century the drama achieved new vigour under the stimulus of Jacinto Benavente y Martínez (1866–1954), Spain's greatest playwright since Calderón, and winner of the Nobel Prize for literature in 1922. With him the drama returned to reality by way of social criticism, declamatory verse giving way to prose, melodrama to comedy, formula to experience, impulsive action to dialogue and the play of minds. After a period of effervescence and irony, Benavente, as he mastered his medium, showed a preoccupation with aesthetics and later with ethics. The extent to which he broadened the scope of the theatre is shown by the range of his plays, *e.g.*, *Los intereses creados* (1907; *The Bonds of Interest*), *Los malhechores del bien* (1905; *The Evil Doers of Good*), *La noche del sábado* (1903; *Saturday Night*), and *La malquerida* (1913) (all translated by J. G. Underhill in *The Plays of Benavente y Martínez*, 4 volumes, 1917–24).

By contrast, Gregorio Martínez Sierra (1881–1947 or 1948) remained true to a more traditional Spanish atmosphere, in which idyllic sentiment, though always deep-rooted in Spanish realities, breathed a sensuous joy in nature and life (*Teatro de ensueño* ["Fantastic Theatre"], 1905; *Canción de cuna* ["*Cradle Song*"], 1911; *El Reino de Dios* ["God's Kingdom"], 1916). The brothers Álvarez Quintero (Serafín, 1871–1938; Joaquín, 1873–1944), writing as one, were pure *costumbristas*. If they contributed nothing new to dramatic art, the *joie de vivre* of their long succession of Andalusian comedies never failed to entertain. Among other dramatists of note are Manuel Linares Rivas (1867–1944) and José López Pinillos ("Pármeno," 1875–1922).

The poetic drama was cultivated by Eduardo Marquina (1879–1946), Jacinto Grau Delgado (1877–1958), Francisco Villaespesa (1866–1936), Ramón María del Valle-Inclán (1866–1936), and Luis Fernández Ardavín (1891–).

Federico García Lorca stands far above any of these. His drama was poetic in more than the formal sense, presenting the elemental passions with an intensity that made the characters poetic symbols of man's tragic impotence to arrest his fate (*Bodas de sangre*, 1933 [*Blood Wedding*]; *Yerma*, 1934; *La casa de Bernarda Alba*, 1936 [*The House of Bernarda Alba*]; all in several English translations). The impulse of renovation visible in the novel after the Civil War failed to reach the theatre, which with Edgar Neville (1889 or 1899–), Joaquín Calvo Sotelo (1905–), and Juan Ignacio Luca de Tena (1897–) remained generally faithful to the patterns established by Benavente and the Álvarez Quinteros. Antonio Buero Vallejo (1916–) and Miguel Mihura (1903–) both attempted to revitalize the drama, Buero Vallejo by social criticism, Mihura by introducing the "theatre of the absurd."

One other vein of dramatic activity, generally thought to fall outside the limits of formal criticism, adds persisting vitality to a long and honourable descent. It is the *género chico* (or "little genre"), heir to the *paso*, *entremes*, and *sainete*, which, within the limitations of the short sketch, frequently with music, achieves a great variety of dramatic effect and for almost a century has charmed the *vulgo* whose way of life supplies it with setting and theme. Ricardo de la Vega (1839–1910) and Carlos Arniches (1866–1943) are outstanding in the kind, which the brothers Álvarez Quintero likewise notably enriched, particularly with their libretti for *zarzuelas* (plays between drama and opera, in which recitative alternates with song).

3. Poetry.—*Modernism.*—Rubén Darío (1867–1916), Latin America's greatest poet, took with him to Spain on his first visit in 1892 the movement known as *Modernismo*, of which he was the leading exponent. In general Modernism was a reaction against 19th-century bourgeois materialism and a search for other, and, more specifically, for aesthetic, values in life. In literature it was a reaction against Naturalism, drawing heavily on French Symbolism and Parnassianism alike (*see* Symbolists, The; Parnassians), with elements of a revived Romanticism. Endowed with

rare technical virtuosity, Darío greatly enriched the musical resources of Spanish verse, notably by his daring use of new rhythms and metres; and under his influence poetry in Spain experienced a renewal comparable with that effected by Garcilaso almost four centuries earlier.

Though so nearly coincident in time with the movement represented by the generation of '98, Modernism had scarcely any contact with it. Initially it stood for the cult of the ivory tower, wherein the poet took refuge from his fellows and from life and sought self-realization in the pursuit of esoteric beauty. It produced, however, one outstanding prose writer, Ramón María del Valle-Inclán, whose four *Sonatas* (1902–05) typify the four seasons of his hero's life. Valle-Inclán later wrote historical novels (the trilogy *La guerra carlista,* 1908–09, the two books of the unfinished series entitled *El ruedo ibérico*), but here, too, his vision was purely aesthetic. For the rest, the Modernists were poets, predominantly Andalusian, the contrast stilll holding between form, which interested them, and content, with which the northerners of the generation of '98 were concerned.

Juan Ramón Jiménez (1881–1958), beginning to write under the aegis of Darío, soon discovered poetry to be for him not a withdrawal, but reality itself, and his style, initially ornate, became more and more bare, with a turning to blank verse, as he strove to capture the poetic essence of each passing moment. Using and gradually winnowing all the resources of Modernism, he became the poets' poet, and a powerful influence on the younger generation. The brothers Machado well exemplify the Andalusian-Castilian dichotomy: Manuel (1874–1947), always at heart a loyal son of his native Seville, was the Modernist; Antonio (1875–1939) early lost his heart to Soria, in Old Castile, and dealt with the recesses of the poet's soul or with the unchanging soul of Castile. Unamuno, Valle-Inclán, and Pérez de Ayala all have their place as poets, though their poems were but the prolongation of their prose works. Of the three, Unamuno, the least accomplished technically, is the most rewarding; he seeks to distill into verse the intensity of his spiritual striving.

The poetic stature of García Lorca grew steadily after his death. He is a poet, as he is a dramatist, of fundamentals, and has shown of what starkness of feeling and effect the *copla* and *romance* are still capable. His *Primer romancero gitano* (1928) and *Poema del cante jondo* (1931) reveal the potency of the inspiration that he drew from Andalusian ways and folklore. The other major poets of the mid-20th century were still those of the pre-Civil War generation, contemporaries of García Lorca and heirs to Darío and to Juan Ramón Jiménez: Pedro Salinas (1891–1951), Jorge Guillén (1893–), Gerardo Diego Cendoya (1895–), Dámaso Alonso (1898–), Vicente Aleixandre (1900–), Rafael Alberti (1902–), Luis Cernuda (1904–63), and Manuel Altolaguirre (1906–). The Civil War dealt hardly with them too, driving some into exile, stifling the inspiration of others; in the main, their best work had already been written by that time. The generation immediately after the Civil War was characterized by minority groups, fugitive reviews, and dispersive tendencies.

Despite the appearance of many new poets during the 1940s and 1950s, especially noteworthy being the group who called themselves *la juventud creadora* and who in 1943 founded the review *Garcilaso,* and the poets associated with the review *Espadaña,* no poet of outstanding stature emerged.

II. CATALAN LITERATURE

1. Medieval Period.—*Poetry.*—The Catalan language is a branch of Peninsular rather than of southern Gallo-Romance. It shows nonetheless many traces of kinship with Provençal (*see* PROVENÇAL LANGUAGE), and the literature in its origins used the *langue d'oc* and the poetic forms cultivated by troubadours north of the Pyrenees: the Catalan troubadors Guillem de Bergadà (1140–1203), Hug de Mataplana, Ramon Vidal de Besalù, Guillem de Cervera, and Cerverì de Girona (1250–80) were as genuinely Provençal poets as were those of Limousin, Quercy, and Auvergne (*see* also TROUBADOURS).

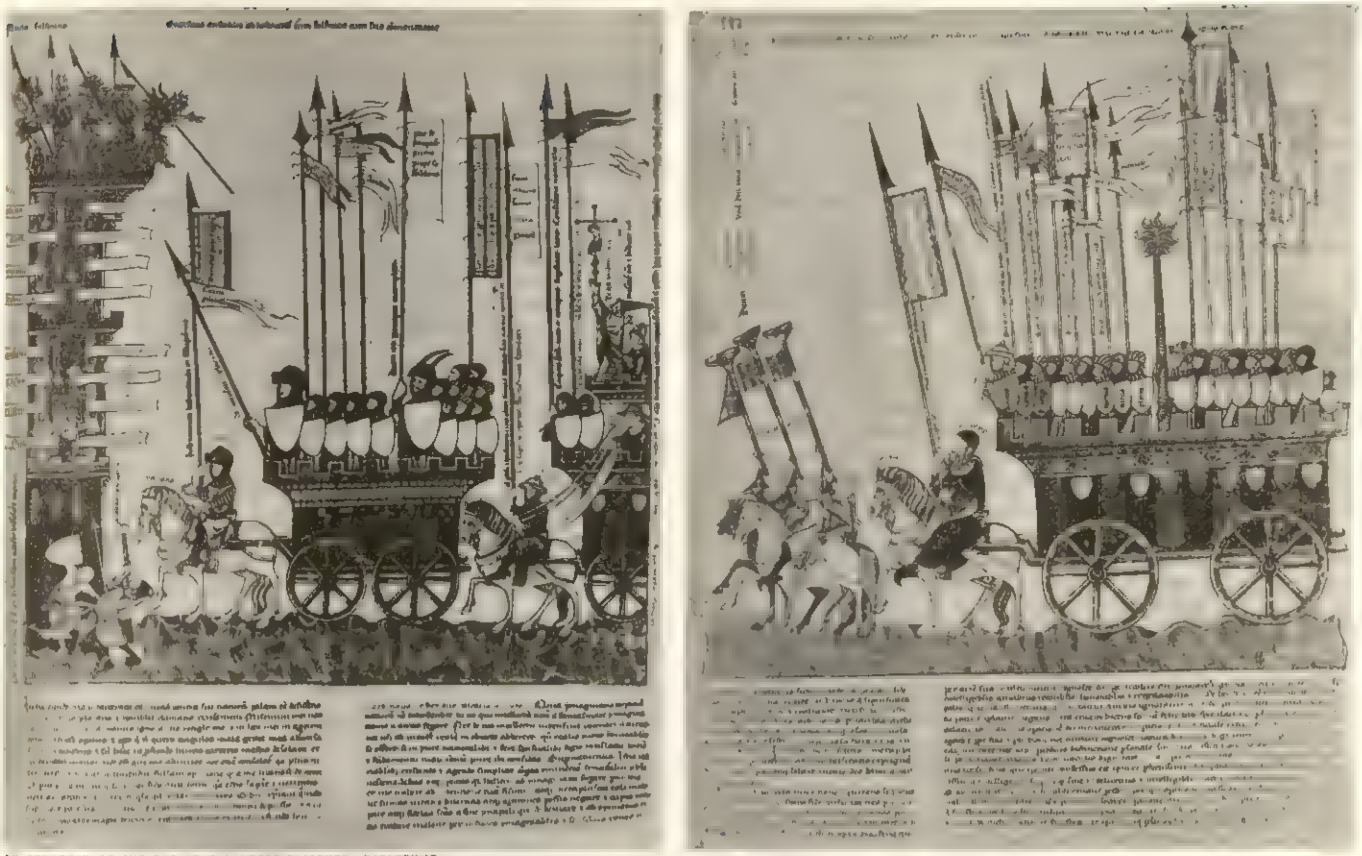
Ramon Vidal was preceptist as well as poet; his *Dreita manera de trobar* became the code for Catalan poets writing in a tongue based supposedly on that of Limoges, and known as *lemosi.* This conventional language of poetry was not proof against the contagion of the spoken tongue, and there resulted a composite idiom well illustrated in the early poetry of Ramon Llull (*c.* 1235–1316). Ramon Muntaner (1265–1336), writing plain Catalan in prose, remains a troubadour in verse. In the later 14th century, there was apparent a gradual waning of Provençal influence and a turning instead for inspiration to northern France, whence derived a cult of long narrative poems on romance themes, including the Arthurian cycle. With the themes came the metre, known as *noves rimades,* a sequence of octosyllabic rhymed couplets. There exist poems of this kind by Pere March (1340–1413), Guillem de Torroella, and Bernat Metge (*c.* 1350–*c.* 1413). Anonymous poems include the *Llibre dels set savis de Roma* ("Book of the Seven Wise Men of Rome"), of more than 3,000 lines, the *Facet o libre de cortesia* ("Book of Courtesy") of about 1,500, and several which carry the new interest in the *langue d'oïl* even to incorporation of passages of French poetry. Another form, the *codolada,* was native in origin; used for narrative but more especially for satire, it combined, again in rhyming couplets, an eight-syllable with a four-syllable line.

The 15th century is the great period of Catalan poetry. It dates from the institution at Barcelona in 1393, under the auspices of John I of Aragon (1387–95), of a poetic academy, the *Consistorio de la Gaya Ciencia,* on the model of that of Toulouse (*see* PROVENÇAL LITERATURE), with *jocs florals* (floral games, including literary competitions). These in themselves produced little poetry of note but typified a new and propitious royal encouragement. This continued under Martin I (1395–1410) and Ferdinand I (1412–16), and contributed to the emancipation of style from alien influences. As the century advanced, Valencia emerged as a new focus of literary activity.

With Johan Berenguer de Masdovelles, Francesc Ferrer, Pere Torroella, Pau de Bellviure, Antoni Vallmanya, and, above all, the Petrarchan Jordi de Sant Jordi (*c.* 1395–*c.* 1440) and Ausiàs March (1397–1459), there developed a school which, as regards versification, is noted for its almost exclusive use of eight-line decasyllabic *cobles* with crossed or "chained" rhymes and a final four-line *tornada* and, in inspiration, shows a turning away from France to Italy. The *Cants d'amor* and *Cants de mort* of Ausiàs March, the most inspired and profound, if also the most difficult, poet of his age in the Iberian Peninsula, contain the finest verses ever written in Catalan; they exerted great influence in 16th-century Castile and continue to influence modern Catalan poets. Very different is *Lo Spill o Llibre de les dones* ("Book of the Natural Gifts"; also called the *Llibre de Consells, c.* 1460) of Jaume Roig (*c.* 1405–78), a bitter and caustic satire upon women, of more than 16,000 four-syllable lines, which derives piquant interest from its vivid portrayal of contemporary Valencian life and manners. Johan Roïç de Corella (1430–1500) is the third great Valencian lyricist, heir to Sant Jordi and March, and perhaps the best representative of the Renaissance spirit, which flowered more fully in Valencia than in Barcelona.

After this bright period, Catalan poetry faded rapidly, the victim largely of political circumstance. From the union of Aragon with Castile there resulted a predominance of Castilian throughout Spain which inflicted a death blow on Catalan literature. The fact that it was a Catalan, Joan Boscà i Almugàver (Castilian, Juan Boscán Almogáver, *c.* 1490–1542), who inaugurated in Castilian a new school of poetry, and that Castilians regard him as a landmark in the history of their Renaissance muse (*see* above), is revealing; by the year of publication of Boscán's works (1543), Catalan poetry had been dead for half a century.

Prose.—The earliest prose works in Catalan are later than the poems of the first troubadours of the Provençal school. Though the oldest document dates from *c.* 1100 (the text of an oath imposed on certain barons by a bishop of Urgel), and the *Homilies d'Organyà* (sermons preserved in an imperfect manuscript, chiefly of linguistic interest) are attributed to the 12th century, literary prose goes back no farther than the close of the 13th. Beginning



BY COURTESY OF THE BADISCHE LANDESBIBLIOTHEK, KARLSRUHE

TWO PAGES FROM A BIOGRAPHY OF RAMON LLULL, "VIDA COETÁNEA," ABOUT 1311

The illumination shows Aristotle, mounted at left, Averroes, mounted at centre, and Ramon Llull, mounted at right, leading an army of personifications of their several philosophies to free Truth from the Tower of Falsehood, where Truth is held captive by an army of demons

as history, often written by prime movers in the events it describes, this prose has the advantage of being original, the language being the everyday speech found in charters from the time of James I's accession to the Aragonese throne in 1213. Its four great 14th-century chronicles are the crowning ornament of medieval Catalan prose. Two—that of James I, apparently compiled shortly after his death in 1276 with the help of memoirs dictated by himself and called the *Llibre dels feyts* ("Book of Facts"); and that of Ramon Muntaner, relating at length the expedition of the Catalan Grand Company to the Morea and the conquest of Sardinia by James II—are distinguished by the artistic skill of their narration and the quality of their language, and invite comparison with those of Villehardouin, Joinville, and Froissart. Bernat Desclot's chronicle deals particularly with the reign of Peter I the Great (1276–85). The account of the reign of Peter IV the Ceremonious (1336–87) is ascribed to Bernat Descoll, but was planned and revised by the king himself. These four works collectively are a perfect expression of the spirit and greatness of medieval Catalonia.

Ramon Llull stands on an eminence apart for his encyclopaedic production, in Catalan, Arabic, and Latin, covering every branch of medieval knowledge and thought. His *Llibre de contemplació en Déu* marks the beginning of Catalonia's golden age of literature; an exhaustive theological treatise, it is also a mine of information on contemporary society. The *Llibre d'Evast e Blanquerna,* his literary masterpiece, laid the foundations of Catalan fiction. *Felix,* or the *Llibre de meravelles* (*c.* 1288) and the *Llibre qui és de l'orde de cavalleria,* a widely translated manual of chivalry, are instructive works with a narrative framework. Inserted in the *Blanquerna* is the *Llibre d'amic e amat* ("Book of the Lover and the Beloved"), a brief masterpiece of mysticism. A century later, Francesc Eximenis (*c.* 1340–1409) represents something of the same intellectual amplitude, if without the originality or driving force, in *Lo Chrestià,* planned as a comprehensive work in 13 books on theology, morals, and politics for the layman, but surviving only in 4, perhaps the only ones written. From its pages emerges a vivid picture of the medieval scene. His *Llibre de les dones,* at once a book of devotion and a manual of domestic economy, is similarly informative on women's way of life.

At the close of the 14th century Bernat Metge inaugurated the Catalan "classical age." Well-versed in Italian literature, he translated in *Valter e Griselda* Boccaccio's story of Griselda from Petrarch's Latin version; in *Lo somni* (1398), which clothes scholastic learning with poetic imagination, he achieved the stylistic masterpiece of Catalan prose. The chivalric romance *Tirant lo Blanc* by Joanot Martorell (d. *c.* 1488) was notable of its kind for the theme, drawn from Muntaner, of the real adventures of the Catalans in the Near East (hence the sparing of it in the famous scrutiny of Don Quixote's library, a satire on the decadent romance). The anonymous late 14th-century *Curial e Güelfa* draws on Desclot, and is the only other Catalan romance in this vein. The beginnings of the drama are represented by the *Misteri d'Elch,* a 15th-century Assumption play based on an earlier *representació;* sung throughout to traditional music, it is still performed at the Feast of the Assumption every year at Elche.

2. Decline: 16th–18th Centuries.—With the loss of political independence, literary and linguistic independence was also lost, and Catalan fell to the level of a patois, kept alive only in the countryside and in the pulpit. The 16th century furnishes a single poet worthy of the name: Pere Serafí, some of whose *Cants d'amor* (1565), written in imitation of Ausiàs March but less obscure, are graceful enough to merit remembrance. In prose, only scholars, chiefly antiquaries and historians, still wrote in Catalan; such were Pere Miguel Carbonell, compiler of the *Chròniques d'Espanya,* Francesc Tarafa (*Crònica de cavallers catalans*), and Anton Beuter, of whose *Crònica general de toda España* the first part (1538; dealing with Valencia) is in Catalan. Forty years of research and abundant documentation give interest to the *Crònica universal del principat de Cathalunya,* a history of the Catalan kingdom, of Jeroni Pujadas, of which also only the first part

(1609) is in Catalan. Thereafter the eclipse was almost complete. Catalan remained only as the language of folksong and ballad; in these—first collected in the *Romancerillo catalán* ("Little Collection of Catalan Ballads"; 1853) by Manuel Milà i Fontanals (1818–84), the historian who played a considerable part in the Catalan revival—it lived on until the reawakening.

3. The Renaixença and After.—In 1814 appeared the *Gramàtica y apologia de la llengua cathalana* of Josep Pau Ballot i Torres, a forerunner of the literary and linguistic renaissance which marked the Romantic period in Catalonia. The pioneers of the rehabilitation of Catalan for literature soon discovered, however, the inadequacies of the ancient language for the expression of their spiritual and intellectual ideas. The very popularity of the satirical poems and farces of a Josep Robreño (1780–1838), for example, was a serious obstacle, because of the corruption of the language in which they were written, as was the later advocacy by Frederic Soler (1839–95) of the use for literature of "Catalan as now spoken" in opposition to literary refinement. The development of modern Catalan literature has been dependent on deliberate enrichment and purifying of the language as a vehicle for contemporary thought; in this the Institut d'Estudis Catalans, founded in Barcelona in 1907, has played a notable part. Bonaventura Carles Aribau's patriotic *Oda a la pàtria* (1832), and the poems of Joaquim Rubió i Ors (1818–99) and Victor Balaguer (1823–1901) prepared the way—as did the reinstitution in 1859 of the *jocs florals*—for the imagination and mysticism of Jacinto Verdaguer Santalo (1845–1902), a great epic poet (*L'Atlàntida*, 1877; *Canigó*, 1886) whose gift is yet essentially lyrical. Miguel Costa i Llobera (1854–1922) cultivated a classical perfection of form; formal beauty is also the mark of his fellow-Majorcan Joan Alcover i Maspons (1854–1926). In Joan Maragall i Gorina (1860–1911) Catalonia found its first great modern poet, one who looks forward rather than back, and whose poetry is suffused with deep spiritual intent. In this spiritual quality, as also, if less happily, in his theory that inspiration absolves the artist from the need for formal perfection, he exerted a powerful influence on later poets. Josep Carner (1884–), Josep-Maria López-Picó (1886–), and Josep-Maria de Sagarra i Castellarnau (1894–1961) are outstanding among many poets of distinction.

The foundations of modern Catalan prose were laid by the critical writings of Rubió i Ors, Francesc Pi i Margall, one of the four presidents of the Spanish Republic of 1873, and Josep Torras i Bages, archbishop of Vich (*La tradició catalana*, 1892). Fiction reached a modest level of achievement late in the century with Josep Pin i Soler (1842–1927), Narcís Oller i Moragues (1846–1930), and Emili Vilanova (1840–1905). One of the best and most influential writers in prose was the essayist Eugeni d'Ors (Eugenio d'Ors y Rovira, pseudonym "Xenius"; 1882–1954), part of whose *Glossari* (1906–17) had already been translated into Castilian before the author abandoned Barcelona for Madrid and himself began to write in that language. His philosophical novel *La ben plantada* (1912) is one of the most notable works in modern Catalan literature.

Catalan dramatists have produced plays of considerable originality. Àngel Guimerà (1847–1924) achieved a European reputation with *Terra baixa* (1896), which inspired a German and a French opera (*Tiefland*, *La Catalane*) and was widely translated. Beginning with historical tragedy (*Gala Placidia*, 1879; *Judit de Welp*, 1883), Guimerà turned to rural drama in *La Boja* (1890), to comedy in *La Baldirona* and *La sala d'espera*, and to modern tragedy in *Maria Rosa* (1894) and *La festa del blat* (1896). The many social dramas of Ignasi Iglésias (1871–1928), inspired originally by the early works of Gerhart Hauptmann, included one near-masterpiece, *Els Vells* (1903). Adrià Gual, author of several works of fantasy, did his best work as director of the *Teatre Intim*, founded in Barcelona in 1898, which familiarized the public with the great drama of all countries and ages. The painter Santiago Rusiñol achieved repute, too, with vivid and imaginative plays.

Hardly had Catalan literature thus won itself once more a place in the sun, when there supervened the dictatorship (1923–29) of Primo de Rivera, who banned the use of any language other than Castilian, and the Civil War of 1936–39. The expatriation of many intellectuals led to the development of a considerable publishing activity in Catalan in Mexico City and Santiago de Chile.

III. GALICIAN LITERATURE

1. Medieval Poetry.—Galician is closely related to Portuguese, and there is no separating the two emergent literatures in the three great repositories of medieval verse, the *Cancioneiros* ["Songbooks"] *da Ajuda, da Vaticana*, and *Colocci-Brancuti* (*see* PORTUGUESE LITERATURE: *Early Period*). Indigenous lyric origins were overlaid by Provençal influence, which had traveled along the pilgrim route to Santiago (*q.v.*) de Compostela, but the dominance of emotion over thought was to remain a constant, so identifying Galician with subjective lyricism that for upward of a century Castilian poets, following Alfonso the Wise (*see* above), made it their medium for works in this vein. Of 116 names in the *Cancioneiro da Vaticana*, 75 have been tentatively identified as Galician; none achieves particular individuality. Macías *El Enamorado* (*fl.* mid-14th century), who died for love and became a legend, was the last Galician troubadour; Galicians thereafter wrote in Castilian, and though echoes of their tradition still abound in the *Cancioneiro de Baena* (*c.* 1445; *see* above), with the Renaissance, and Castilian political hegemony, there descended a sleep even more profound than that affecting Catalan.

2. The Modern Revival.—The Romantic movement, like the Peninsular War, revived local feeling and interest in things Galician, but not in the language. The *Xogos Froraes* (floral games; the equivalent of the Catalan and Provençal *jocs florals*) of 1861, with the first dictionary (1863) and first grammar (1864) of Galician, mark the change. Francisco Añón y Paz (1812–78) was the first notable poet in the resurrected idiom, his most stirring notes being love of country and of freedom. Rosalía de Castro (1836–85; *see* also above), the greatest name in Galician literature, identified herself to a rare degree with the spirit and people of the Galician countryside in *Cantares gallegos* ("Galician Songs"; 1863); her *Follas novas* ("New Leaves"; 1880), introspective to the verge of despair, reflected deep personal sorrows. Eduardo Pondal y Abente (1835–1917) stood somewhat apart: bard of a dimly sensed heroic past, he communed with nature and Celtic mythology (*Queixumes dos pinos*, 1886; *Os Eoas*, an unfinished symbolic epic on the discovery of America). Valentín Lamas Carvajal (1849–1906) is remembered as the voice of the peasant, whose daily life, woes, and simple joys inspired, with growing disillusion, his *Espiñas, follas e frores* ("Thorns, Leaves, and Flowers"; 1871), *Saudades gallegas* ("Galician Sorrows"; 1889), and *A musa das aldeas* ("The Muse of the Villages"; 1890). In Manuel Curros Enríquez (1851–1908) a rebellious temperament, at issue especially with the church, informed the *Aires da miña terra* ("Airs from My Land"; 1880) and *O divino sainete* ("The Divine Farce"; 1888), but he shows too, with genuine feeling for nature, a gentle, pervading melancholy.

Prose showed no comparable achievement. Aurelio Ribalta (1864–1940?), Manuel Lugrís Freire (1863–1935), and Heraclio Pérez Placer expressed in the short story very similar veins of inspiration, but were overshadowed by novelists of stature—Emilia Pardo Bazán, Ramón María del Valle-Inclán—who chose to write for a larger public in Castilian; so too, in her five novels, did Rosalía de Castro.

The 20th century has produced, especially since 1920, a continuing abundance of Galician poets, not yet sufficiently differentiated, who underline the identification of Galician literature with a markedly poetic regional temperament and language.

SPANISH MAIN, the name applied during the period of Spain's empire in the Western Hemisphere to the mainland of Spanish America, particularly to northern South America west of the mouth of the Orinoco River and to what is now Central America and Mexico. Early Spanish expeditions first gave the name to these regions. During the development of the Spanish colonial trade the name was also applied to the Caribbean Sea, across which moved the bulk of Spain's colonial commerce in gold, silver, spices, tea, hides, etc. Spain's chief commercial ports on the Caribbean, most of which were strongly fortified against enemy and pirate raids, were Cartagena, Portobelo, Port Royal (Jamaica), Veracruz, Havana, and San Juan (Puerto Rico). (C. F. J.)

SPANISH MOSS, the name given to an epiphytic, herbaceous plant (not a true moss), *Tillandsia usneoides,* of the bromelia family (Bromeliaceae). It hangs in long festoons from the branches of trees in tropical and subtropical American forests, being especially conspicuous on the live oak in the southeastern United States. The whole plant is covered with scaly hairs for the absorption of water, giving it a gray colour. It is used, after processing, as an excellent substitute for horsehair stuffing.

Ramalina reticulata, a lichen called Californian Spanish moss, grows supported on trees in humid valleys of the western coastal range of the United States.

SPANISH SAHARA, an overseas province of Spain on the low, desert Atlantic coast of northwest Africa, comprises the Southern region of Río de Oro, between Cape Blanc (Blanco) and latitude 26° N near Cape Bojador; and the Northern region of Saguia el Hamra, between that line and the 27° 40′ N line of latitude, the boundary with Morocco. Spanish Sahara is bounded by Algeria for a few miles in the northeast and otherwise entirely by Mauritania. The total area is 102,703 sq.mi. (266,000 sq.km.; Río de Oro 71,043 sq.mi. [184,000 sq.km.], Saguia el Hamra 31,660 sq.mi. [82,000 sq.km.]). The capital of the province is El Aiún (Aiun), and it is administered by a governor general.

Along the coasts are occasional cliffs and bold headlands, as at Cape Bojador, but sand dunes are also common. In both regions the coastal plain has rocks of Cretaceous or later age, though they are often masked by sand. These rocks have been prospected for oil, especially in the northwest. The east has Paleozoic and Precambrian rocks, rises to about 1,450 ft. (440 m.), and is rugged with several deep ravines, all permanently dry. Rain occurs only rarely. In the interior the daily range of temperature is commonly 11° to 44° C (52°–112° F). Only along the coast are conditions more temperate, as the result of the influence of the sea, the cool Canary Current, and the northeasterly trade winds.

The total population (1960) was 23,793 mostly in Saguia el Hamra, excluding nomads who spend most of the year in the province. The capital of Río de Oro is Villa Cisneros (pop. [1960] 1,961), a small settlement with white-domed buildings that stands on a 23-mi. (37 km.)-long peninsula. In Saguia el Hamra there is a permanent settlement at Smara, as well as at El Aiún (pop. [1960] 5,251). Most of the people of both regions are Berbers, more or less arabized with some Negro admixture. All, except about 5,300 Europeans, are Muslims.

In neither region is there any agriculture to speak of. Camels, goats, and sheep are raised, and there is some export of their skins, as well as of dried fish. Between Villa Cisneros and the mainland is Río de Oro Bay, which provides a sheltered but shallow anchorage. The town is connected with the rest of the region, with the Canary Islands, and with Spain by air, and there are tracks north to Cape Yubi (Juby) and south to Tichlá and La Agüera, as well as several caravan routes. A shipping service links Villa Cisneros with La Agüera and the Canary Islands.

History.—Río de Oro Bay was discovered by the Portuguese in 1436, mistaken for a river, and named Rio de Ouro ("River of Gold") on account of gold dust obtained from the inhabitants. The Spaniards had already begun the colonization of the Canary Islands, and in 1476 they established the fort of Santa Cruz de Mar Pequeña on the mainland. It was abandoned in 1524, and the territory remained independent until the 19th century. In 1878 a British trading post was established by Donald Mackenzie on Cape Yubi, but it was surrendered to the ruler of Morocco in 1895. Meanwhile French travelers had visited Saguia el Hamra. The Spaniard C. Benitez and others explored the coast in 1882,

and E. Bonelli signed treaties with the inhabitants on behalf of the Sociedad Española de Africanistas. In 1884 a Spanish protectorate was declared over the coastal zone from Cape Bojador to Cape Blanc and nominally subordinated to the captain general of the Canaries. A factory was established at Villa Cisneros in 1885, but it was abandoned in the face of attacks by the Africans. Spanish claims were challenged by the French, who claimed a protectorate over the Sahara, and a Franco-Spanish convention of 1900 established the landward frontier of Río de Oro, awarding the salt deposits of Ijil (Fort Gouraud) to the French. Other agreements (1906 and 1912) resulted in French recognition of Spanish rule in Saguia el Hamra. The strip of desert country bounded on the north by the Wadi Draa and by parallel 27° 40′ on the south was ceded to Morocco in 1958.

(H. V. L.; R. J. H. C.)

SPANISH SUCCESSION, WAR OF THE (1701–1713), the name given to the European war that arose out of the disputed succession to the throne of Spain and to the Spanish Empire following the death (1700) of the childless Charles II of Spain. The war was primarily a struggle to determine whether these vast possessions should pass to the House of Bourbon or to the House of Habsburg, both of which had dynastic claims (*see* genealogical table below), or whether they should be partitioned to preserve the balance of power in Europe.

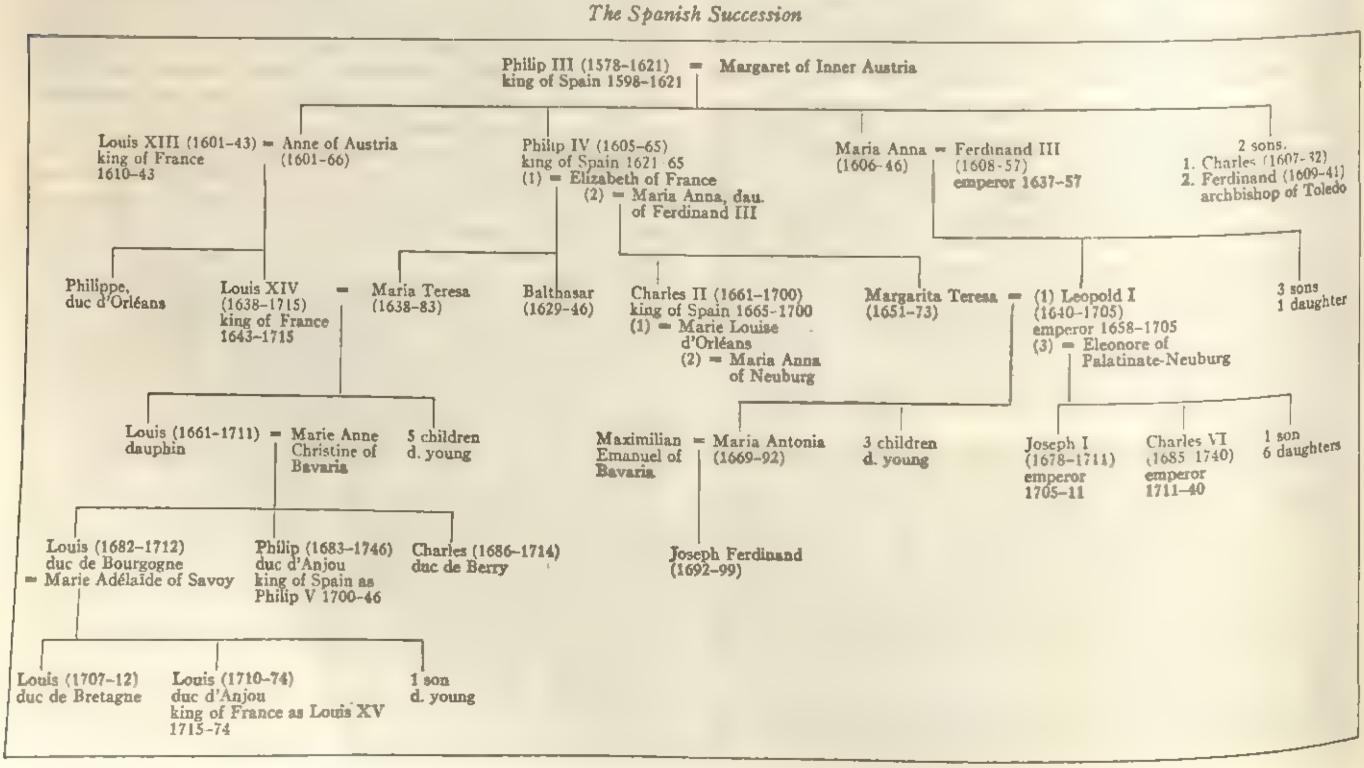
Dynastic Claims.—Of the two daughters of Philip III of Spain (Charles II's grandfather), the elder, Anne, married Louis XIII of France, and the younger, Maria Anna, married the future Habsburg emperor Ferdinand III. Two sons of these marriages, Louis XIV and the emperor Leopold I, respectively, married their Spanish cousins Maria Teresa and Margarita Teresa, the daughters of Philip IV and sisters of Charles II. Maria Teresa explicitly renounced her claim to the Spanish succession on her marriage to the French king, as her aunt Anne had done on the occasion of her marriage to Louis XIII. But Margarita Teresa (d. 1673) made no renunciation and, moreover, was named in Philip IV's will as the next heir after his son Charles (Charles II of Spain). Consequently, when Margarita's daughter Maria Antonia (d. 1692), who in 1685 married the Bavarian elector Maximilian Emanuel, gave birth in 1692 to a son, the electoral prince Joseph Ferdinand, this prince could be regarded as heir presumptive to Charles II. Leopold I, however, had persuaded Maria Antonia to bestow her right to her mother's succession on him, and on the sons of his third marriage, with Eleonore of Palatinate-Neuburg; but the validity of this bestowal, on which the immediate Habsburg claims to the succession were based, was dubious. The Bourbon claim was similarly dubious, being based on a disregard for the French queens' acts of renunciation. The claim of the electoral prince Joseph Ferdinand, on the other hand, appeared superior to both.

In the precarious lifetime of Charles II, French influences at the Spanish court were heavily counterbalanced in the field of international politics by the attitude of the Maritime Powers, England and the United Provinces of the Netherlands. United after 1688 under the personal rule of William III, they were strongly opposed to the Bourbon claim, fearing not only the aggrandizement of French power but also the loss of their well-established trade with Spain and the Indies. Louis XIV, becoming convinced that a Bourbon success would result in a general European coalition against him, and to avoid the Spanish possessions passing to a Habsburg, in October 1698 agreed with William III in a Partition Treaty (signed at The Hague) to recognize Joseph Ferdinand's rights to Spain, the Spanish Netherlands, and the Indies. Milan, however, was to go to the archduke Charles (later the emperor Charles VI), the emperor's younger son (who would presumably be excluded from the imperial throne by his elder brother Joseph); and the rest of Spanish Italy, as well as the Basque province of Guipúzcoa, was to go to the dauphin Louis (1661–1711).

Spain was indignant at this partition treaty, and in November 1698 Charles II made a will naming Joseph Ferdinand heir to the whole inheritance. But in February 1699 Joseph Ferdinand died. A second Partition Treaty (October 1699) between France and England, which was subscribed in March 1700 by the United Provinces, offered Spain, the Spanish Netherlands, and the Indies to the archduke Charles; the dauphin was to get all Spanish Italy except Milan, instead of which he would have Lorraine. The emperor, whose approval of the First Partition Treaty had been sought in vain, now also declined to accede to the second, hoping to win the whole succession for the archduke Charles. To counter this new partition, Charles II in October 1700 made another will, leaving the Spanish dominions, which were to be undivided and to be kept separate from any other crown, to Philip, duc d'Anjou, the second son of the dauphin Louis; failing Philip, to his younger brother Charles, duc de Berry; failing Charles, to the archduke Charles.

When Charles II died on Nov. 1, 1700, Louis XIV was con-

The Spanish Succession



fronted with a dilemma. If he accepted the will, he was faced with the prospect of war with the emperor, who might have the support of the Maritime Powers. If he refused the will and stood by the Second Partition Treaty, the inheritance (by the terms of the will) would pass to the Habsburgs, and France would have to fight for those possessions promised by the treaty. As war appeared inevitable in either case, Louis chose the former alternative, acknowledging Philip of Anjou as Philip V of Spain. The war might have remained a struggle between the king of France and the emperor if Louis had not acted with haughty arrogance and provoked England and the United Provinces to enter the war. In December 1700 Louis solemnly acknowledged the rights of his grandson Philip to remain in the line of succession to the crown of France. On the death (September 1701) of the exiled James II of England, Louis recognized James's son as King James III. During 1701 he also made it clear that French merchants would in future enjoy exclusive rights to share in the slave trade to the Spanish colonies in America.

Strategy of the War.—The War of the Spanish Succession has the complexity of any major war fought between two groups of allies whose interests and ambitions are sometimes in sharp conflict. It was fought on five fronts —the Low Countries, the Rhine, the Danube, Northern Italy, and Spain—as well as at sea. It was a war of some considerable movement, for it was conducted according to the strategic conception of the 18th century, which advocated maneuver and countermaneuver to contain an enemy, rather than the Napoleonic strategy of striking at the enemy's main force regardless of losses. Armies of the 18th century, before the days of national conscription, were too difficult to replace for generals to be eager to risk heavy casualties if these could be avoided. One very interesting fact that emerges in the study of the War of the Spanish Succession is how often John Churchill, 1st duke of Marlborough (*q.v.*), favoured a strategy that was much more forceful and "Napoleonic" than was usual in the early 18th century, and it is clear that his bold plans were sometimes too unorthodox for his imperial ally, Prince Eugene of Savoy (*q.v.*). Other points of interest are the relative importance of the various allies in determining the outcome of the war, the number of times that military operations were interrupted by attempts at peace negotiations, and the extent to which the final outcome of the war was decided not by victories in the field but by political developments in the capitals of the combatants. It is a curious fact that the fate of Spain was decided principally by campaigns in the Low Countries or on the Danube, with very little regard to what was actually happening in the Peninsula itself.

FIG. 1.—SOUTH-CENTRAL EUROPE DURING THE WAR OF THE SPANISH SUCCESSION

THE COURSE OF THE WAR

1701. The Emperor and Louis XIV Begin Hostilities.—The war may be said to have begun in March 1701 when French troops took over from Spanish forces the fortresses in the Spanish Netherlands; but for the rest of that year the war was essentially one between Louis XIV and the emperor Leopold I, and its principal theatre was Northern Italy, where the French had been able to get control of the Spanish possessions in the valley of the Po. Prince Eugene assembled an Imperial Army in Tirol and marched south with great secrecy through the territory of neutral Venice along the east bank of the Adige River. Marshal Nicolas Catinat (*q.v.*), commanding the French, failed to attack a numerically inferior Imperial force that, by a feint at Chiusa, had distracted his attention from Eugene's main move on Verona (May 28), nor did he cross the Adige and force battle on Eugene's main army, though this too was inferior in numbers to his own. Eugene maintained the initiative and forced the French to retreat westward behind the Mincio River. He then succeeded in following them

across this river (July 28), so that, to defend Milan, Catinat had to fall back still farther westward beyond the Oglio River (Aug. 16). These humiliating maneuvers were reported to Louis XIV by Catinat's enemies at the French court, and he was replaced by François de Neufville, duc de Villeroy (*q.v.*); but when the new commander tried to take the offensive, he was sharply defeated at Chiari (Sept. 1). The campaigning season ended with the Imperialists in command of most of the duchy of Mantua, and during the winter of 1701–02 Eugene executed a brilliant raid on Cremona, where he captured Villeroy, a success that led the dukes of Modena and Guastalla to declare for the emperor.

1702. The War Becomes General.—By 1702 the efforts of the diplomats had transformed the struggle into a general European war. France and Spain had the support of two reluctant allies, Portugal and Savoy, who feared to oppose the Bourbons, whose forces controlled Spain and the Spanish possessions in Northern Italy. Two allies who were to be of more value to France were the Wittelsbach brothers, Maximilian Emanuel, elector of Bavaria, and Joseph Clement, elector of Cologne. The emperor had the support of the United Provinces and England by the Treaty of The Hague (September 1701), and of Frederick I of Prussia and a great many minor German princes. But the first year of the general struggle saw little decisive action. In Italy Eugene's communications with Vienna were cut by Louis Joseph, duc de Vendôme (*q.v.*), who had taken over Villeroy's command; nevertheless, Eugene was able to maintain himself and to harass the French. At sea an English expedition under Adm. Sir George Rooke against Cádiz (August–September 1702) was a failure, but Rooke managed in October to destroy the Spanish silver fleet that had taken refuge in Vigo harbour.

In the Low Countries the Maritime Powers were outnumbered by the French so that there was a serious threat to Holland. This had a deep effect on the Dutch deputies, who remained excessively cautious and timid throughout the war. The Franco-Spanish forces had two fortified lines, one running from Antwerp to Huy, on the River Meuse, the other from Antwerp along the Scheldt and Lys rivers to Aire. In July Marlborough assembled an army near Nijmegen and attacked southwest toward Diest, driving back Louis François, duc de Boufflers (*q.v.*), toward his fortified lines. Marlborough outmaneuvered him and reached the lines first, but the Dutch refused to allow him to give battle, being satisfied that by these maneuvers Marlborough had forced Boufflers to abandon his threat to the United Provinces. The Maritime Powers did, however, succeed in capturing Kaiserswerth (June) and Rheinberg on the lower Rhine and thus improved their communications with the emperor.

The 1702 campaign on the Rhine opened uneventfully, but the end of the summer saw a development that was next year to become one of the most important operations of the war. An Imperial Army under the margrave Louis of Baden, which had been gathered round the Neckar River, crossed the Rhine north of Speyer (June 1702) and threatened Alsace. Catinat, now in charge of the German front, was uncertain whether to mass the French forces on the Lauter or the Ill River, and Louis of Baden successfully besieged and captured Landau in September. It was at this point that the development took place that was to grow into the major campaign of 1703–04. The elector of Bavaria now openly declared for France and captured Ulm. This threat in his rear forced Louis of Baden to retreat to the east side of the Rhine. Louis Hector (later duc) de Villars (*q.v.*), who had superseded Catinat, followed the retreating Imperial Army, crossed the Rhine at Hünningen and defeated the Imperialists at Friedlingen (Oct. 14, 1702).

1703. The Tide Turns in Favour of the French.—In 1703 fortune began to favour the French, although in three theatres of war the Imperialists and the Maritime Powers managed to achieve minor successes. In the Mediterranean the English fleet was able to blockade the French fleet in Toulon, and this convinced the Portuguese government that England could provide effective protection against the Bourbons. In May 1703 Portugal, therefore, relinquished its uneasy alliance with France and joined the Maritime Powers. On the lower Rhine Marlborough invaded the electorate of Cologne and in May captured Bonn. By the end of the summer Marlborough, though impeded by the cautious Dutch generals, had managed to push the French out of the country between the Meuse and the Rhine. In Italy Vendôme was justifiably suspicious of the loyalty of his ally Victor Amadeus II, the duke of Savoy, and demanded that he should hand over Turin and Susa to the French and even disband his troops. This demand eventually decided Victor Amadeus to abandon his uneasy alliance with France and join the emperor. This he did in October, but it was too late in the year to have any effect on military developments in Italy that season.

These minor successes of the emperor and his allies, however, were more than outweighed by the French and Bavarian threat to Vienna itself. In March Villars had crossed the Rhine at Kehl and, pushing across the Black Forest, had in May joined the elector of Bavaria near Ulm. The Imperialist forces under Louis of Baden had offered no resistance but had remained to the north in the lines of Stollhofen, on the Rhine, watched by a French force under the comte de Tallart. The situation facing the emperor was very grave, but the elector of Bavaria lacked Marlborough's dash. Instead of pushing on down the Danube and striking direct at Vienna, the elector decided first to establish control of Tirol so as to safeguard his communications with Milan. This more cautious strategy might have been justified, for the elector was able to reach the Brenner Pass at the beginning of July, but Vendôme's force, which he had hoped would be there to join him, did not manage to push north through Italy till some weeks later. By this time the elector had been forced to retreat toward Bavaria. The possibility of seriously threatening Vienna, however, was still not out of the question. Though by now Louis of Baden and the Imperial general Hermann Styrum had brought up their forces to cover any attack on Vienna, they had failed to combine, so that Villars was able to attack Styrum and defeat him at Höchstädt, near Blenheim (Sept. 20). Villars was in favour of making a dash for Vienna, but the elector of Bavaria refused. There was a quarrel, and Villars, one of the most brilliant of the French commanders, was recalled. On the Rhine in September Tallart took Breisach and in November defeated General Thüngen at Speyerbach and recaptured Landau, but these minor French successes could not repair the damage done by the elector of Bavaria's excessively cautious strategy on the Danube.

1704. The French Threat to Vienna Checked.—When the campaigning season opened in 1704, the serious effects of the elector of Bavaria's delays of the previous year were not yet apparent, and it looked as if the French and Bavarian threat to Vienna was as dangerous as ever. In April strong French forces crossed the Black Forest and, in May, joined the elector of Bavaria near Dillingen. Louis of Baden failed to stop the junction of these two forces, and, though Eugene himself had been moved to the Danube front to replace Styrum, it seemed impossible with the forces available that he would be able to stop the French and Bavarian armies from striking at Vienna. Another French force under Tallart was to the north, near Kehl, to protect the communications between France and the French Army on the Danube. A third French force, under Villeroy, was in the Netherlands, holding Marlborough. It was at this point that Marlborough showed his genius for appreciating the strategy of the war as a whole and his consummate skill in moving troops with unexpected speed and complete secrecy. Marlborough knew that he would never be able to gain the consent of the Dutch to a move to relieve Vienna from the French and Bavarian threat if this seemed to leave Holland unprotected. Therefore, he pretended that he was going to turn the flank of Villeroy's force by a move up the Moselle. Marlborough moved across the Meuse to the Rhine and made his way up that river, reaching Mainz at the end of May. Tallart, from his position farther south, at once moved across to the left bank of the Rhine, fearing that Marlborough intended to attack Alsace, but Marlborough only made a feint of attempting to cross the Rhine at Mannheim. Instead, from Mainz he pushed southeast across the Main River, up the valley of the Neckar, across the watershed between the Neckar and the Danube, and by the middle of June joined forces with Louis of Baden just north of Ulm.

The Imperial commanders had been able to discuss plans with Marlborough during his march, and it was decided that Eugene should move westward to contain Tallart at Stollhofen, while Marlborough and Louis of Baden were to attack the French on the Danube. Marlborough was able to take Donauwörth (July 2), thus forcing the French and Bavarian troops, under the elector and the comte de Marsin, Villars' successor, to retreat south up the Lech River, which enabled Marlborough to get between his enemies and Vienna. At this point the French forces were increased, for Villeroy, once he had realized that Marlborough had given him the slip, moved south from the Netherlands to join Tallart on the Rhine in Alsace. Tallart, therefore, was free to cross the Rhine at Kehl (July 6) and join the elector of Bavaria near Augsburg (Aug. 6). On his march Tallart made the serious mistake of wasting five days trying to capture Villingen. As a result, Eugene, who had marched from Stollhofen along the north bank of the Danube, was able to reach Höchstädt and join forces with Marlborough on the same day that Tallart joined the elector. Marlborough's force was then large enough for him to detach Louis of Baden, an uncongenial colleague, to besiege Ingolstadt, the one strong place on the Danube east of Donauwörth held by the Bavarians, and which was a serious threat to communications with Vienna. The French and Bavarians, learning that Louis of Baden had gone, moved north to attack Eugene, crossing the Danube at Dillingen. Marlborough had remained south of the Danube to cover the siege of Ingolstadt but was not out of touch with Eugene and was able to move to his assistance. A forced march brought his army to the north of the Danube and into line with that of Eugene near the village of Blenheim. Marlborough and Eugene attacked the enemy at the Battle of Blenheim (*q.v.*) on Aug. 13, 1704, and achieved a victory that shattered the reputation of the French Army and compelled the French to withdraw to the west of the Rhine. By the end of 1704 the whole situation on the Danube front had been altered. Vienna was no longer in danger. The French invasion had been destroyed, and the elector of Bavaria was now a fugitive in France, the whole of his electorate falling into the hands of his enemies.

Developments in Spain and the Mediterranean during 1704 were also fairly encouraging for the Imperialists and their allies. The accession of Portugal to the side of the Imperialist and Maritime Powers meant that it was now much easier to launch an invasion of Spain itself, and in February the archduke Charles was escorted to Portugal by an English squadron under Rooke to attempt the conquest of Spain. He achieved little on land, and Rooke, who had been ordered to sail from Lisbon into the Mediterranean and join the duke of Savoy in an attack on Toulon, found Savoy unable to spare troops for his enterprise. But on his way back to England, Rooke managed to capture Gibraltar (Aug. 4) and to defeat the French fleet off Vélez-Málaga (Aug. 24), which gave England command of the Mediterranean for the rest of the war.

1705. Stalemate.—Marlborough had intended to launch an attack from the Rhine against France itself by way of Metz, but the Dutch failed to produce enough supplies, and the Rhenish electors did not provide sufficient transport. Moreover, the death of the emperor Leopold I in May 1705 had the effect of deflecting Imperialist forces to cover the election of the new emperor (Joseph I) at Frankfurt. Marlborough, therefore, transferred his attention to the Netherlands, where he succeeded in piercing the French lines at Tirlemont (July 18); but because of the excessive caution of his Dutch allies, Marlborough was not able to make full use of his success. In Italy Eugene pushed the French from the Oglio River as far west as the Adda River, thus relieving some of the pressure on Savoy, where Turin was under siege by the French.

1706. A Year of Disaster for the French.—In spite of French successes in Italy, where Vendôme in April 1706 drove the Imperial Army back into Tirol, Marlborough still had plans for joining forces with Eugene, expelling the French from Northern Italy, and threatening Toulon. In the same month, however, Louis of Baden retreated eastward across the Rhine, and the Dutch were, therefore, too nervous to consider Marlborough's unorthodox scheme. Instead, England provided subsidies that enabled the emperor to buy 24,000 troops from German princes. In July Eugene attacked south down the left bank of the Adige, once more disregarding Venetian neutrality as he had in 1701. This time he struck south across the Po (July 18), then moved with astonishing speed westward up that river to join the duke of Savoy at Villastellone, south of Turin, and in September raised the siege of Turin. This victory decided the issue in North Italy. By the Convention of Milan in March 1707 Louis XIV gave up his attempt to control North Italy and withdrew all his troops.

In the Netherlands Villeroy, receiving information that Marlborough had not yet been reinforced by Prussian and Hanoverian forces, struck toward Liège but was heavily defeated by Marlborough at the Battle of Ramillies (May 23, 1706). Marlborough pursued the retreating enemy so hard that they were unable to reform on the line of the Lys River but had to retreat still farther to Courtrai. The result of this victory was that in less than two weeks Marlborough was in command of all Spain's province of Brabant and most of its possessions in Flanders. Antwerp, Ghent, Bruges, Oudenaarde all capitulated, and in July the fall of Ostend improved Marlborough's communications with England. At the end of August he obtained Menen; in September, Dendermonde; and in October, Ath. The victory in the Spanish Netherlands was overwhelming, and Marlborough's success helped Eugene's 1706 campaign in Italy, because, after the Battle of Ramillies, Vendôme was recalled from Italy to replace the discredited Villeroy. Marlborough's victory also had the effect of paralyzing the French forces on the Rhine, for troops were transferred from that quiet sector to reinforce the shattered French forces in the Netherlands.

In Spain the Imperialists and their allies also achieved successes in 1705–06. A siege of Gibraltar by Bourbon forces was relieved in March 1705. Henri de Massue, earl of Galway (*q.v.*), commander of the allied forces in Portugal, advanced from Portugal into Estremadura and compelled the comte de Tessé to abandon Andalusia. The English admiral Sir Cloudesley Shovell took a squadron into the Mediterranean and enabled Charles Mordaunt, 3rd earl of Peterborough (*q.v.*), to capture the fort of Montjuich near Barcelona in September and to take Barcelona in October 1705, thus inducing the traditionally separatist Catalonia and Valencia to declare for the archduke Charles. In 1706, though Tessé besieged Barcelona, he was compelled to withdraw in May when an English fleet forced the French ships supporting Tessé to retire to Toulon. In June Imperialist and English forces seized Madrid, though Galway was unable to maintain his hold on the capital and had to withdraw to Valencia.

1706. The Opening of Peace Negotiations.—So decisive were the reverses experienced by France and its allies in 1706 that in August Louis XIV made an approach to the Dutch for peace. He was prepared to cede Spain and Spanish America to the archduke Charles if Philip retained Milan, Naples, and Sicily. The Dutch were offered a strong "barrier" of fortresses in the Spanish Netherlands, but the English and Imperial governments would not consider terms that envisaged the partition of the Spanish Empire.

1707. The Imperialists and Maritime Powers Suffer Reverses.—In Germany the emperor's situation became critical because of developments in the Northern War (*q.v.*), which was raging in the Baltic. Charles XII of Sweden had established himself in Saxony in September 1706, and there was a serious danger that where the elector of Bavaria and French troops had failed in their attack on Vienna, Charles might succeed. The emperor was already short of troops because many minor German princes were reluctant to hire troops to him when they might be needed for their own defense. But Charles XII was not prepared to collaborate with France to attack Vienna, and the crisis passed. Its effects were felt, however, on the Netherlands front, where the absence of German troops made it impossible for Marlborough to achieve anything of note against Vendôme. On the Rhine the Imperial forces were weakened by the death (January 1707) of Louis of Baden, whose successor in command, Margrave Charles Ernest of Brandenburg-Bayreuth, proved considerably less able.

FIG. 2.—THE LOW COUNTRIES DURING THE WAR OF THE SPANISH SUCCESSION

Villars managed to take the lines of Stollhofen in May and was able to raid the whole of Swabia until the margrave of Bayreuth was superseded by George, elector of Hanover (later George I, king of Great Britain). In September Villars withdrew in good order to the west of the Rhine after some of his troops had been diverted to the Provence front (*see* below).

In Spain the emperor and his allies experienced considerable reverses. Galway and the archduke Charles quarreled and separated, the archduke retiring to Catalonia. This left Galway with only 15,000 men, who were decisively defeated by James Fitz-James, duke of Berwick (*q.v.*), at the Battle of Almansa, in Murcia (April 25, 1707), partly because most of Galway's Portuguese troops did not engage the enemy. Aragon, Valencia, and Murcia were lost to the allies, and in Catalonia they were compelled to remain on the defensive. In Northern Italy the emperor, having gained control in 1706, decided that Eugene should launch an attack against Toulon. Unfortunately, Savoy delayed sending help, and some Imperial troops under Wierich, Graf von Daun, were also diverted to capture Naples. After the defeat at Almansa the help Eugene expected from Spain was not forthcoming, and instead French troops returning victoriously were able to reinforce Tessé at Toulon. Eugene's siege of Toulon (July–August) had finally to be broken off, and the only success achieved by Eugene's thrust was the scuttling of the French fleet in the harbour.

1707–08. Peace Negotiations Resumed.—In spite of the improvement in French fortunes during 1707, Louis XIV was still eager to end the war, and in the winter of 1707–08 envoys from Louis and Philip V made a fresh overture to the Dutch, baited with offers of commercial advantages at the expense of Spain. But once again the negotiations were checked by the uncompromising attitude of England, where in December in the House of Lords the Whigs passed a resolution refusing to make a peace by which a member of the House of Bourbon should retain any of the Spanish possessions.

1708. The Imperialists and Maritime Powers Achieve Further Successes.—A project for a three-pronged offensive against France planned early in the year proved impracticable, partly because Saxony and Prussia did not provide their proper contingents. Instead, Eugene began his march from Italy to join Marlborough in the Spanish Netherlands, where Vendôme had managed at the beginning of July to recover Bruges and Ghent and so regain control for France of most of the Spanish possessions in West Flanders. Though Eugene's troops had not yet arrived, Marlborough moved to check Vendôme's advance and defeated the French at the Battle of Oudenaarde (*q.v.;* July 11, 1708). Marlborough then wanted to invade France itself and launch a simultaneous invasion of Normandy, but his plan was considered by Eugene to be too unorthodox. The Imperialists and their allies, therefore, concentrated instead on besieging Lille, which finally fell on Oct. 22; this forced the French to relinquish their hold on the Spanish possessions in West Flanders and to retire to France

1709. Third Peace Negotiations.—The weakness of France was clearly shown in the peace terms that Louis XIV was now prepared to consider. When the French envoys, Antoine Louis Rouillé and Jean Baptiste Colbert, marquis de Torcy, again approached the Dutch (March 1709) at The Hague, though at first they once more demanded at least Naples and Sicily for Philip V, they finally made it clear that Louis XIV was prepared to relinquish the whole of the Spanish inheritance. But again the English and Dutch proved implacable. They insisted that Louis XIV should obtain the surrender of the Spanish throne by Philip, and that, if Philip refused, Louis should agree to use force to expel him. It now seems clear that the English secretary of state, Charles Townshend, the emperor, and the Dutch were chiefly responsible for these unrealistic terms and that Marlborough, though he did not exert his influence enough, had a sounder appreciation of what could be reasonably expected from France. As it was, on May 28 Louis XIV rejected the terms offered, and the war was resumed.

1709. Hostilities Resumed.—The lull in hostilities caused by the peace negotiations of 1709 were used by the French to make a prodigious effort to put yet another army into the field under Villars, who took up a strongly defended position in the Netherlands. Marlborough wanted to attack along the French coast, supported by the English fleet, but this plan was again too unorthodox to win the approval of his allies, and instead the Imperialist and Maritime forces besieged Tournai (July–September) and later moved against Mons. Villars advanced against his opponents and met them at Malplaquet, southwest of Mons. Marlborough was in favour of joining battle at once, but this was vetoed, and Villars gained two vital days in which to strengthen his position, with the result that when the Battle of Malplaquet (*q.v.*) was eventually fought on Sept. 11, 1709, although Marlborough achieved a victory, it was at the cost of 20,000 casualties as compared with about 11,000 French. In October Mons fell, but the campaign had been disastrously costly to the Maritime Powers and the Imperialists.

On other fronts the Imperialists achieved very little. The duke of Savoy failed to cooperate with Daun in a move against Dauphiné, and though an Imperial Army under Claudius, Graf von Mercy, crossed the Rhine near Basel, it was defeated at Huningue (Aug. 26). In Spain Galway's Portuguese troops had proved unreliable, and it was decided in 1708 to send them home and replace them with German troops from Italy, released by the

Imperial successes of 1706–07. Early in 1708, therefore, Galway returned to Portugal, but before the Germans under Guido, Graf von Starhemberg, had arrived in Spain, the Bourbons took Tortosa (July 1708), thus separating Catalonia from Valencia. Even after the arrival of the German forces, the Bourbons were able to take Denia (November 1708) and Alicante (April 1709). In September 1708 the English had captured the island of Minorca, but in Spain itself, although some French troops had been withdrawn because of the critical military situation in the Netherlands in the summer of 1709, Starhemberg achieved little during 1709, and Galway, who had invaded Estremadura from Portugal, was sharply defeated on the Caya River (May 17).

1710. Fourth Peace Negotiations.—By this time not only the French were weary of the war. The Dutch, having in October 1709 by the First Barrier Treaty been guaranteed by England the right to garrison nine towns in the Spanish Netherlands and ten more if these were recovered from the French, were less than ever interested in prosecuting the war. Even some of the English statesmen, including Townshend, Sidney Godolphin, earl of Godolphin (*q.v.*), and Marlborough, were prepared to consider allowing Philip V to retain part of the Spanish possessions. But the emperor was vehemently opposed to any partition of the Spanish Empire. The duke of Savoy was bitterly opposed to allowing Sicily to pass to Philip, seeing any increase in Philip's territories in the Mediterranean as a menace to himself. Philip himself, having achieved considerable successes in Spain and being sure of the enthusiastic support of many of the Spaniards, was as obstinately opposed to the idea of dividing the Spanish possessions as was the emperor. Peace negotiations (March–July 1710) were held at Geertruidenberg in the United Provinces between representatives of Louis XIV and the Dutch. Louis XIV went so far as to offer a subsidy to pay troops to drive Philip out of Spain. The Maritime Powers insisted on his using French troops to do this. Marlborough might have been able to make saner councils prevail, but by 1710 his own personal position had been undermined by political events in England (*see* below), and he was not strong enough to overrule his allies. In July 1710 the peace negotiations broke up.

1710–11. The Whole Situation Altered in Favour of France.—By the end of 1710 Philip V was firmly established in Spain. Starhemberg had at first won some successes at Almenara in July and at Saragossa in August, and Imperialist troops had actually been able to occupy Madrid for a second time in September. But, as in 1706, they had been forced to evacuate the capital, and on their retreat eastward they had been defeated at Brihuega (Dec. 8–9) and at Villaviciosa (Dec. 10), so that by the end of 1710 the Imperialists were again confined to Catalonia.

But more decisive for the outcome of the war than victories or defeats in any of the fields of battle were the political developments that were taking place in England. The Whig government's conduct of the war had provoked much criticism, partly because it was thought that not enough use had been made of the victories of 1708, partly because Malplaquet had been regarded as so costly in casualties that it had been looked upon as a defeat rather than a victory, and partly because the First Barrier Treaty with the Dutch in 1709 was criticized as sacrificing English trade with the Netherlands and English friendship with the emperor. There was always a fear that if the Dutch controlled the Spanish Netherlands they might exclude British merchants. The heavy taxation necessary to finance the war had grown increasingly unpopular. The Whigs who made up the ministry were divided among themselves. Marlborough's wife Sarah lost her influence over Queen Anne, and Marlborough found that his personal influence at court had disappeared. During the summer of 1710 the Tory Charles Talbot, duke of Shrewsbury, was appointed lord chamberlain, and the Whigs Godolphin and Charles Spencer, 3rd earl of Sunderland, were removed from office. The Parliament that met in November 1710 was strongly Tory. On April 17, 1711, the emperor Joseph I died without male issue. This event revolutionized the whole international situation, for the heir presumptive was Joseph's brother, the archduke Charles, and no English or Dutch government would continue a war to put the Spanish Empire under the control of the prince who would also be the ruler (as Charles VI) of the Holy Roman Empire and the hereditary possessions of the Habsburgs in Austria, Bohemia, and Hungary.

1711–13. Effective Peace Negotiations.—The death of Joseph I dramatically improved the prospects of the fifth peace negotiations, which had begun at the end of 1710, when communications were established between the governments of France and England. In the Netherlands Marlborough achieved his final success against the French, breaking Villars' *ne plus ultra* defensive lines, which extended from the coast to Valenciennes, by a series of skilful maneuvers (July–August 1711), but on Dec. 31, 1711, Marlborough was dismissed from his command. The peace negotiations continued throughout 1711, and on Jan. 29, 1712, peace discussions were opened formally at Utrecht, in the United Provinces, between representatives of France, England, and the United Provinces. There was at the beginning no representative of Portugal, Savoy, or of the German princes, but it is more remarkable that there was no representative either of the emperor or the king of Spain. The situation became complicated by the deaths of the dauphin Louis (April 1711), his eldest son Louis, duc de Bourgogne (February 1712), and the latter's elder surviving son, Louis, duc de Bretagne (March 1712). This left the French claimant to the Spanish throne, Philip V, the eldest surviving brother of the duc de Bourgogne, next in succession to the French throne if his nephew Louis (later Louis XV), the sickly younger son of the duc de Bourgogne, should die. Through English pressure, Philip renounced his claims to the French throne in May, although the French legal experts considered that no renunciation, however formal, could cancel a hereditary claim based on divine right.

Both Louis XIV and the English Tory government were now determined to end the war. Louis was even prepared to make peace without Philip. Henry St. John, Viscount Bolingbroke (*q.v.*), who was in charge of the English negotiations, adopted an equally ruthless attitude toward his ally, the emperor Charles VI, for early in May 1712 Bolingbroke instructed the duke of Ormonde, who had succeeded the duke of Marlborough as commander in chief, not to take part in any future battle. In November Philip's renunciation of his claim to the French throne was formally made before the Spanish *Cortes*, and later in the same month his younger brother Charles, duc de Berry, renounced any claim to the throne of Spain. In March 1713 Louis XIV's recognition of these renunciations was formally registered by the French *Parlement*. The peace terms on which England and France finally agreed were advantageous to England but were also much more favourable to the Bourbons than the terms that Louis XIV had been prepared to accept in 1710 when he had been ready to pay for troops to expel his grandson from Spain, or in 1709 when he would have been satisfied if Philip could have been allowed to retain Naples and Sicily, or even in 1706 when Louis had been prepared to be satisfied with Naples, Sicily, and Milan for his grandson.

THE TREATY OF UTRECHT

A more accurate name for the series of treaties signed between 1713 and 1714, which finally concluded the war, would be the peace settlement of Utrecht. Most of the documents were signed at Utrecht, but two were signed in the German cities of Rastatt and Baden, and one in Madrid.

On April 11, 1713, France concluded treaties of peace at Utrecht with England, Holland, Prussia, Portugal, and Savoy. By the treaty with England, France recognized the Protestant succession in England and undertook to give no further help to the Stuarts. France ceded Newfoundland, Nova Scotia, the island of St. Kitts, and the Hudson Bay territory to England and promised to demolish the fortifications at Dunkerque (Dunkirk). The Anglo-French treaty was supplemented by a treaty of commerce. In the treaty with the Dutch, France agreed that the United Provinces should annex part of Gelderland and should retain, as a barrier against any future French invasion, certain fortresses in the Spanish Netherlands; these latter territories were to be assigned to

the emperor when he made peace. By a commercial treaty the French conceded to the Dutch privileges similar to those enjoyed by England. In the treaty with Prussia, France acknowledged Frederick I's royal title (king in Prussia from 1701) and recognized his claim to some small territories, including Neuchâtel and upper Gelderland. In return France obtained the principality of Orange. In the treaty with the duke of Savoy, France accepted that he should rule Sicily and Nice. The treaty with Portugal recognized its sovereignty on both banks of the Amazon.

The peace treaties between Spain and its opponents were not signed until a few months later, but an understanding with England had been prepared by the Asiento (*q.v.*) agreement, by which Spain gave to Britain the exclusive right of supplying the Spanish colonies with slaves. The treaty of peace was finally concluded in Utrecht on July 13, 1713. In it Spain ceded Gibraltar and Minorca to England and promised to cede Sicily to Savoy. England and Spain concluded a commercial treaty in December 1713. But though by July 1713 so many peace treaties had been concluded, there were still delays, and Louis XIV was sharply critical of Philip for holding up the negotiations with the Dutch and for quibbling over the terms already conceded to Savoy. On Aug. 13, 1713, the Spanish treaty was concluded with Savoy, Victor Amadeus II overlooking some modifications made by Philip in order to secure Sicily. The peace between Spain and the Dutch was delayed till June 26, 1714, and that between Spain and Portugal until February 1715.

But even then the general pacification was not complete, for the emperor remained at war both with France and with Spain. Eugene was defeated in the Netherlands by Villars at the Battle of Denain (July 1712) and on the Rhine lost Landau (August 1713) and Freiburg (November 1713). On March 7, 1714, the emperor concluded a peace treaty with France at Rastatt. The emperor recovered Breisach, Kehl, and Freiburg and in return ceded Strasbourg and Alsace to France and agreed to allow France's allies, the electors of Bavaria and Cologne, to recover their possessions. In addition, the emperor was recognized by France as ruler of the former Spanish possessions of Milan, the bases in Tuscany, Naples, the Spanish Netherlands, and Sardinia. On Sept. 7, 1714, the princes of the empire accepted these peace terms and concluded with France the Treaty of Baden. On Nov. 15, 1715, a treaty (known as the Third Barrier Treaty) between the United Provinces and the emperor laid down that seven fortresses near the French border were to be garrisoned by the Dutch. This "barrier" was guaranteed by Great Britain.

The Treaty of Baden is usually considered the last of the treaties of the settlement of Utrecht. The emperor remained technically at war with the king of Spain until 1720, but the peace settlement of Utrecht laid the foundation for international relations in southern Europe until about 1733.

Thus 12 years of war and all the brilliance and courage of Marlborough and Eugene had less effect on the development of the international situation than domestic and personal politics in London and the fortuitous death of the emperor without male issue. In spite of Blenheim, Ramillies, Oudenaarde, and Malplaquet, Philip V retained the major part of what he had been bequeathed —Spain itself and all Spain's possessions in America. All he had to cede were the Spanish Netherlands, the Spanish possessions in Italy, Gibraltar, and the islands of Sicily, Sardinia, and Minorca.

SPARKS, JARED (1789–1866), U.S. historian and president of Harvard, was also an editor and, to his contemporaries, the "American Plutarch." He was born at Willington, Conn., on May 10, 1789. He attended Phillips Exeter Academy and graduated from Harvard College in 1815. Sparks was installed as minister of the First Independent Church (Unitarian) of Baltimore, Md., in 1819, resigning the post in 1823. From then until 1830, under his ownership and editorship, the *North American Review* became the arbiter of literature in New England. He fostered the growing interest in the American Revolution with his multivolumed "lives and letters" of Franklin, Washington, and Gouverneur Morris, 12 volumes of that war's diplomatic correspondence, and 25 volumes entitled *The Library of American Biography*. Occupying the McLean chair at Harvard, 1839–49, he was the first U.S. professor of secular history. On Feb. 1, 1849, Sparks was chosen president of Harvard. He was harried by administrative difficulties and ill health, and his presidency, lasting four years, closed his most fruitful years of scholarship. He died at Cambridge March 14, 1866.

Sparks believed that patriotism obliged him, when editing source materials, to omit passages likely to cause international ill will and sometimes to "embellish" what "the Fathers" had actually written. Therefore, the exacting scholarly standards of a later age rendered obsolete much of what he had edited. To his admirers, however, he was the patriarch of American history and the peer of his friend George Bancroft (*q.v.*).

Sparks's own manuscripts and papers are at Harvard. His private library and maps are at Cornell University, Ithaca, N.Y.

SPARROW, any of several small, chiefly drab birds having thick bills well adapted for seed eating. They occur in several families of songbirds (suborder Passeres). The true sparrows (*Passer*) are cosmopolitan members of the weaverbird family (Ploceidae). The house, or English, sparrow (*P. domesticus*) is common throughout temperate parts of Europe, Asia, North America (introduced from England in 1851), South America, and Africa. In North America it has replaced many native birds to a considerable extent in cities and towns. This prolific bird (it raises several broods a year) has a pugnacious disposition and is adaptable to urban areas, thriving best in the neighbourhood of man. City birds become sooty, but in the country the male has a gray crown, black throat mark, white cheeks, a chestnut nape, brown upperparts, and a buffy belly; the female and young are dull brown above and dirty white below, with no distinctive head marks. The nest is an untidy tangle of grass, feathers, hair, etc., which may contain three to seven whitish eggs flocked with gray. House sparrows spend much time hopping about on the ground feeding, all the while flicking their tails and uttering repetitive "cheeps." The tree, or mountain, sparrow (*P. montanus*), both sexes of which resemble the male house sparrow except for the brownish crown and doubly barred wings, is a local species in Britain but has been introduced elsewhere.

JOHN H. GERARD

HOUSE SPARROW (PASSER DOMESTICUS)

The numerous native American sparrows belong to the subfamily Emberizinae, of the finch family (Fringillidae). Foremost among them is the song sparrow (*Melospiza melodia*), a variable bird with more than 30 subspecies; its song is sprightly and musical and is among the first heard in spring. The chipping sparrow (*Spizella passerina*), a perky little bird easily told by its chestnut cap and white stripe along the eye, nests in trees in gar-

JOHN H. GERARD
WHITE-THROATED SPARROW (ZONOTRICHIA ALBICOLLIS)

dens and is a common bird in the suburbs. The Savannah sparrow (*Passerculus sandwichensis*), abundant in the Maritime Provinces of Canada, breeds from northern Alaska and most of Canada south to Mexico; about 16 subspecies are recognized in the U.S. and Canada. The grasshopper sparrow (*Ammodramus savannarum*) is common enough, but its skulking habits and insect-like buzzing and ticking calls cause it to be overlooked. One of the handsomest of sparrows is the white-crowned sparrow (*Zonotrichia leucophrys*), with pearl gray breast and bands of black and white on the crown; resembling it closely is the white-throated sparrow (*Z. albicollis*), with an additional white throat patch.

The hedge sparrow, or dunnock (*Prunella modularis*), belonging to the accentor family (Prunellidae), is a small, brown-backed bird with an iron-gray head and neck. It is widely distributed throughout Europe and can be distinguished from true sparrows by its thin, dark bill and shuffling, rather than hopping, gait.

A few species of the weaver finch family (Estrildidae) are called sparrow, including the well-known Java sparrow (*Padda oryzivora*), a handsome, finely feathered gray bird with a black head and large pinkish bill; it is a popular cage bird. (HT. FN.)

SPARROW HAWK, the smallest—and perhaps commonest—of the American falcons, is a little larger than an American robin, rusty-red barred with black on the back and tail, lighter underneath, with a striking face pattern of black and white. It is *Falco sparverius*. Although often swallowlike in flight, it may hover on rapidly beating wings as it surveys fields below for prey. Its ringing call—*killy-killy-killy*—is often heard. Grasshoppers and mice form its chief food, though occasional small birds may be eaten. Sparrow hawks are often found in open suburban areas—even in cities, along railroad or superhighway rights of way. It is not unusual to find one perching on a telephone pole or on a wire. The nest site is a tree hole, ground hole, crevice among rocks, or some secluded nook in a building. There, without benefit of nesting materials, four or five eggs are laid—ivory to light brown, with brown to dull red speckles—which are incubated about 30 days. The hatchlings are down covered but gradually assume adult-type plumage. The young remain in the nest for about 25 days, the females eating the lion's share of the food brought by the parents and rapidly attaining the larger size characteristic of its sex in adult falcons. This species is similar to the European kestrel (*q.v.*). (W. J. BE.)

SPARTA, the capital of Laconia (*q.v.*), was for long the most powerful city of ancient Greece. The name refers in Greek to the city alone, the alternative name LACEDAEMON to both city and territory; "Spartiate" designated a member of the ruling aristocracy, but the people and state were normally "the Lacedaemonians," this term including the subject perioeci (*q.v.*).

Sparta lay at the northern end of the plain of the Eurotas (Evrotas) river on its western bank, where the routes into Laconia from north and northwest join. The central territory was this plain, between the high peaks of Taygetus (Taiyetos) to the west and Parnon to the east, reaching the sea at the port Gythium (Yithion) to the south. Sparta also controlled the mountainous district eastward, with the coast to Cape Malea; some Arcadian border districts to north and northwest; Messenia (*q.v.*) to the west: altogether about two-fifths of the Peloponnese. The Eurotas valley and the Messenian plain of Stenyclarus are, for Greece, conspicuously fertile, and their climate kindly.

Prehistory.—Sparta itself has produced no Mycenaean remains: Amyclae, a few miles south, and Therapne, above the east bank of the Eurotas, were then the important centres, the latter perhaps the capital of the kingdom assigned in the *Iliad* to Menelaus, though no palace comparable to those of Mycenae or Pylos had been found by 1960.

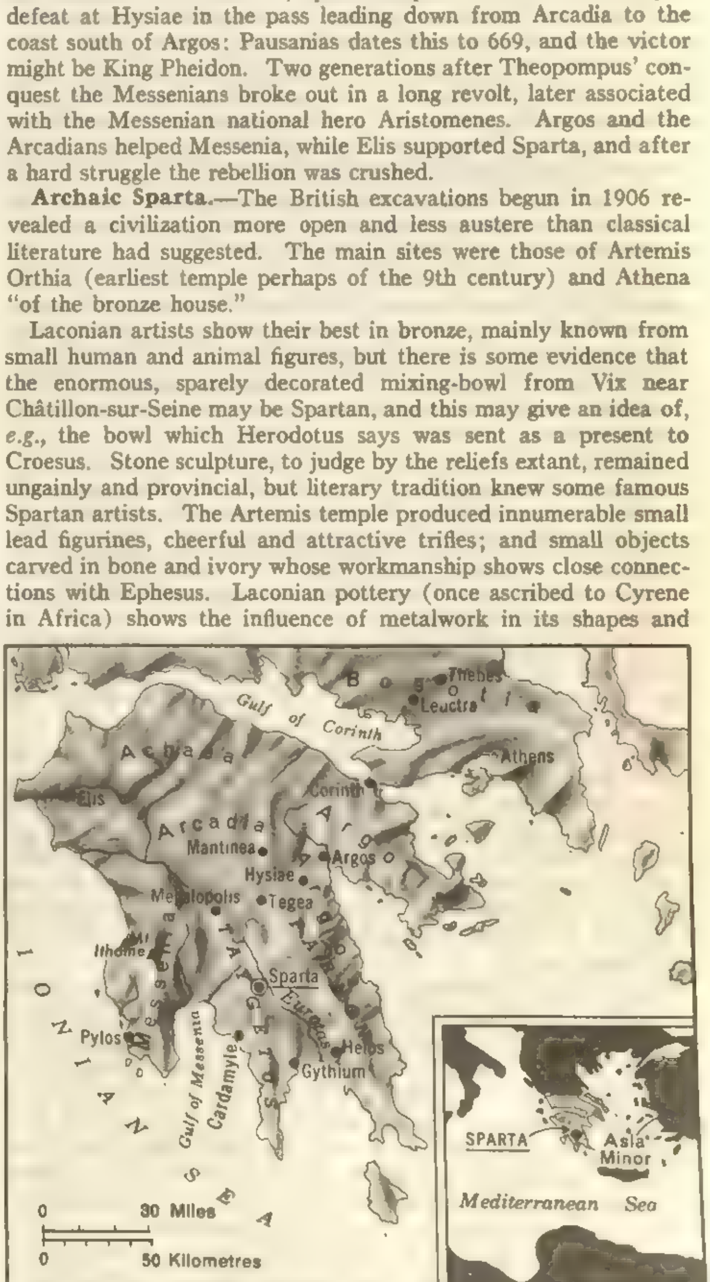
Tradition ascribed the foundation of Sparta to Dorian invaders claiming descent from Heracles (*see* DORIANS). The Dorian dialect, spoken at Sparta, belongs to that division of the Greek-speaking peoples which entered Greece last; and at the Amyclaeum the latest Mycenaean pottery is followed by a variety of Protogeometric which marks a fresh start and does not, like some varieties elsewhere, show stylistic continuity with Mycenaean. The earliest finds from Sparta show some, but not much, contact with the outside world.

Detailed accounts by later Greek writers of Sparta's gradual conquest of Laconia have an improbable ring. Spartan tradition made much of the capture of Amyclae, in the later version the work of the eighth generation of kings, but more likely an incident of the original conquest: importance was also attached to the capture of Helos in the south, in the belief that the serfs called helots (*q.v.*) took their name from it.

Conquest of Messenia.—The First Messenian War (*c.* 735–715) under King Theopompus marks the beginning of authentic Spartan history, though it represents the completion of the conquest rather than Sparta's first venture west of Taygetus. Samos helped Sparta, and the war may be connected with the contemporary Lelantine War (*q.v.*). The best land was divided among the Spartiates, and the Messenians joined the helots in servitude. After the war Tarentum in south Italy, the only Spartan colony, was founded. To the east, Spartan expansion was checked by a defeat at Hysiae in the pass leading down from Arcadia to the coast south of Argos: Pausanias dates this to 669, and the victor might be King Pheidon. Two generations after Theopompus' conquest the Messenians broke out in a long revolt, later associated with the Messenian national hero Aristomenes. Argos and the Arcadians helped Messenia, while Elis supported Sparta, and after a hard struggle the rebellion was crushed.

Archaic Sparta.—The British excavations begun in 1906 revealed a civilization more open and less austere than classical literature had suggested. The main sites were those of Artemis Orthia (earliest temple perhaps of the 9th century) and Athena "of the bronze house."

Laconian artists show their best in bronze, mainly known from small human and animal figures, but there is some evidence that the enormous, sparely decorated mixing-bowl from Vix near Châtillon-sur-Seine may be Spartan, and this may give an idea of, *e.g.*, the bowl which Herodotus says was sent as a present to Croesus. Stone sculpture, to judge by the reliefs extant, remained ungainly and provincial, but literary tradition knew some famous Spartan artists. The Artemis temple produced innumerable small lead figurines, cheerful and attractive trifles; and small objects carved in bone and ivory whose workmanship shows close connections with Ephesus. Laconian pottery (once ascribed to Cyrene in Africa) shows the influence of metalwork in its shapes and



SPARTA AND THE PELOPONNESE

its precise decoration, painted on a white ground. It developed unevenly, influenced by Corinthian art but generally conservative, and seldom achieved satisfactory composition: the well-known cup depicting Arcesilaus of Cyrene watching the weighing and storage of wool is at least fresh and lively. After the middle of the 6th century it declined like all fabrics except Attic.

Of native craftsmen, Gitiadas who made Athena's Bronze House in the middle of the 6th century was best remembered. From abroad, Theodorus of Samos built a famous portico, and Bathycles of Magnesia late in the 6th century the elaborate throne for Apollo at Amyclae. Many foreign poets and musicians came, among the earliest Terpander and Polymnastus from the eastern Greek world, Thaletas from Crete, but these are little more than names. Late in the 7th century Alcman, probably of Lydian origin, is known from the long fragment of a *partheneion* ("maiden song") and many shorter quotations: he had much to say of Spartan girls, horses and food, and was more sensitive to landscape than most Greeks. But Tyrtaeus' military exhortations, composed during the Messenian revolt, are native work, though later he was inappropriately claimed as an Athenian.

Within its fairly narrow limits, this society shows a gay and lively mind, open to the outside world. But the Messenian revolt underlined the dangerous position of a small aristocracy which excluded the free perioeci from government and held down a helot population many times its own number, and this must have hampered Spartan development. The evidence of archaeology and Alcman, however, provides no decisive evidence about the date at which Sparta was bound by its other peculiar institutions.

Political and Military Institutions.—In the 5th century and later, the Spartans believed that their whole system of life was the work of a single early lawgiver, Lycurgus (*q.v.*). Some modern historians substantially accept the Greek theory, as it was eventually fixed, that he carried out a large reorganization in the 9th century; but the readiness of the Greeks to ascribe everything Spartan to Lycurgus, and the character of the institutions themselves, make this doubtful. The institutions may not all be of the same date, and it is possible that later reformers sheltered behind Lycurgus' name, fostering the ascription of everything to him, their own reforms included.

Two kings held equal power, from the separate families of the Agiadae and Eurypontidae. The origin of this unique system is lost in the dark ages. Later the kings held certain priestly and other privileges, and a Spartan army abroad was almost always commanded by one of them: Aristotle characterizes them as "hereditary generals." The two families to the end produced many gifted and influential leaders.

Greek aristocracies regularly curtailed the king's power by setting up other executive magistrates, and there is evidence that the Spartan ephors (*see* EPHOR) once represented "the city" as against the kings.

The *gerousia* (*q.v.*) no doubt descends from a council of nobles summoned in Homeric fashion by the kings. The assembly included all Spartiates over 30 who had undergone the prescribed training and paid their dues to *phiditia* (*see* below). It could pronounce only on issues set before it by the *gerousia*, but in practice it discussed and decided all major questions, such as war and peace. It often tried kings whose conduct had caused dissatisfaction; and through the election of ephors it indirectly controlled the administration.

The relation between kings, *gerousia* and assembly in the process of reaching decisions of state is the main subject of the Great Rhetra which Plutarch quotes as an oracle given to Lycurgus; it also refers to the numbers of the *gerousia* and to tribal organization. It has been accepted as a 9th-century document, but its provisions seem more appropriate to the 7th century, and it is here taken as an enactment of that time, one of the pillars of the classical constitution, designed to secure Sparta from the discontents which in many cities produced tyranny by guaranteeing, under certain limitations, the rights of the assembly.

The army, based originally on the three kinship tribes common to all Dorian communities, was regrouped when the citizen body was reorganized on a local basis, the five villages (*obai*) of Sparta. This system probably dates from the 7th century (*obai* are mentioned in the Rhetra) and was in force at the battle of Plataea (479), where the perioeci fought in separate units but in equal numbers with the Spartiates. Before the end of the 5th century there were six regiments called *morai*, in which Spartans and perioeci served together, and at Leuctra (371) the Spartan element was little more than a cadre.

The navy was commanded by an admiral who held office for one year only.

Social Institutions.—Spartiates lived under state supervision from birth, when weakly children were exposed on Taygetus. From 14 to 20, graded in year-groups, they underwent a severe training in discipline and endurance. Thereafter they might be admitted to the messes called *phiditia* in which male Spartans ate and passed much of their lives, and on admission they became full citizens, called "equals" (*homoioi*): it is not clear whether in the classical period there was any large residue of those who failed for admission or had not land enough to pay their dues, in kind, but a class of "inferiors" is mentioned once in the 4th century. Foreigners were sometimes allowed to undergo this training, even some selected helots (*mothakes*), but these could not become citizens.

"GIRL RUNNING," SPARTAN BRONZE. ABOUT 500 B.C.; FOUND IN ALBANIA: HEIGHT 4½ IN.

Similar but less strict institutions existed among the Dorians of Crete, and there are many parallels outside Greece, so that the system may be a general inheritance which elsewhere lapsed so early that it was forgotten. But at Sparta it served military needs, and it may have been deliberately preserved and strengthened there. The assertion of equality must also have been a deliberate assertion at some particular date: in practice it proved increasingly difficult to maintain.

The evidence for Lycurgus' division of land into equal lots is suspect, coming mainly from the time of the 3rd-century reformers (*see* below). But land was the basis of a Spartan's citizenship, and for long there were conventional or legal restrictions on its alienation. The accumulation of other forms of wealth was hindered by Sparta's retention of a clumsy currency of iron spits when other Greeks, from the 7th century onward, coined silver; and by the prohibition of private ownership of precious metal. Spartiates might not engage in trade, and there were sumptuary laws, *e.g.*, against elaborate building.

Over-all, this was a hardy society, freed to an unusual extent from the Greek preoccupation with agriculture, using its leisure for hunting and the perfection of its rigorous military training. Plato complained that Lycurgus educated his citizens in the warlike virtues to the neglect of the others.

Peloponnesian League and Persian Wars.—When Croesus of Lydia in the 540s sought Greek help against the rise of Persia, he found that Sparta was the strongest city and made his alliance with it. By the end of the 6th century Sparta headed an organized league covering most of the Peloponnese and reaching out beyond it. The Spartans' rise was due primarily to their military power. They suffered one heavy defeat in the middle of the 6th century when they tried to reduce Arcadian Tegea to a status like that of Messenia, but Herodotus says that their other wars of this period were successful, and they had mastered Tegea before Croesus' appeal. The basis of the settlement with Tegea was alliance, not subjection, an important stage in the development of the Peloponnesian league. They also defeated Argos in the Thyreatis, a border district on the coast which the Spartans now firmly held: this involvement, they said, prevented them from helping Croesus when Cyrus of Persia overthrew him.

A policy of deposing tyrants is ascribed to the powerful Chilon,

who was ephor *c.* 556 (he has also been credited, but by a misunderstanding of the evidence, with increasing the power of the ephorate). Sicyon was liberated soon after 556; an unsuccessful attempt was made, with Corinthian help, to overthrow Polycrates of Samos in 525; Hippias was driven from Athens in 510. It is not a very full record, but Sparta gained the reputation of supporting constitutional government against tyranny, and this must have helped the growth of the league.

King Anaxandridas, who died soon after 520, played some part in all this, but his attitude is not clear and it may not have been consistent. His energetic son Cleomenes I (*q.v.*) quarreled with Athens after its liberation and made several attempts to coerce the Athenians, thwarted mainly by his colleague Demaratus and the Corinthians. These differences were perhaps the occasion for giving a formal constitution to the Peloponnesian league, for the first recorded league conference occurred about 500. If these developments damaged Sparta's prestige, it was restored by Cleomenes' victory over Argos at Sepeia without allied help (*c.* 494), and at the end of his reign he was on good terms with Athens, at whose request he took hostages from Aegina when the Aeginetans gave tokens of submission to King Darius shortly before Marathon (490). But to achieve this he had to get his opponent Demaratus deposed, and overstrained the great personal influence he had in Sparta: the opposition triumphed, and after a brief exile and restoration he committed suicide in prison. The troubles in which this reign ended probably included also a Messenian revolt in 490, but ten years of quiet enabled Sparta to recover, and in 480 the Greeks accepted without question Spartan leadership during Xerxes' invasion.

Since Cyrus' first conquest of Asia Minor frequent appeals had been made to Sparta for help against the Persians. This is the more striking, since after the failure of the expedition against Samos in 525 Sparta consistently refused to send help overseas: this was presumably from military calculation rather than indifference, and several Spartan actions of this period can be interpreted as intended to build up resistance to Persia inside Greece. Above all, Sparta had never shown any sign of compromising with the Persians.

For the operations of 480 and 479 *see* GRECO-PERSIAN WARS. Sparta's performance has been criticized, but under Spartan leadership the war was won: Spartan heroism at Thermopylae was never forgotten, and the last land battle at Plataea was very much Sparta's victory, under the regent Pausanias. But Salamis had demonstrated Athenian naval power. Athens came forward as the leader of the eastern Greeks, and in 478, though Pausanias' expedition to Cyprus and Byzantium was a military success, his conduct so much alienated the non-Peloponnesian allies that they formed the Delian league (*q.v.*) under Athens.

Struggle With Athens.—The Spartans acquiesced in the transfer of the naval hegemony to Athens, and this withdrawal must have weakened the great influence they had acquired. Pausanias (*q.v.*) probably wished to fight Athens instead, but the peace party prevailed, and his eventual disgrace and death did further harm to Sparta's prestige. The Spartans had now to fight to retain their position even inside the Peloponnese.

The Spartan army, trained for a set battle in the Greek heavy infantry style, was ill-adapted for distant and scattered operations, and the Spartans failed to improvise the machinery necessary for the running of an overseas alliance. The peace party saw further expansion as a danger to Sparta's traditions, and trusted the Athens of Cimon (*q.v.*); and the helots were an ever-present menace. Democracy was another danger: in the 6th century the Spartans could appear as the leaders of a crusade for constitutional government, but in the 5th they were left on the defensive as a bulwark of oligarchy, for they could not accept democracy without disrupting their whole system.

Democracy was adopted in Elis (471) and Mantinea: Themistocles, in exile at Argos, had perhaps some hand in this. Tegea also revolted, with some help from Argos, and Arcadia had to be subdued in two hard-fought battles. In 464 a disastrous earthquake caused heavy casualties at Sparta and precipitated a Messenian revolt. Defeated in the field, the rebels were hard to dislodge from their stronghold on Mt. Ithome, and the Spartans called for help from their allies, Athens included. But they then dismissed the Athenian contingent, distrusting its loyalty, and this insult wrecked Cimon's policy of co-operation with Sparta. The Athenians allied themselves with Sparta's enemy Argos (462/461).

The Spartans, having weathered the crisis but still dangerously weakened, took no direct part in the ensuing war except in 457, when they tried to revive the Boeotian league as a counterweight to Athens: but they had a hard fight at Tanagra to secure the army's return, and Athens soon after overran Boeotia. Disaster in Egypt (454) checked Athens' progress, and a truce was made in 451 for five years. In 446 Sparta invaded Attica in support of a Megarian revolt from Athens, but retired without a battle and concluded the Thirty Years' peace, which implicitly recognized the Athenians' right to their empire.

The breakdown of this peace in 431 and the outbreak of the Peloponnesian War (*q.v.*) have been variously explained. Thucydides thought the basic cause was Spartan distrust of Athens, and this is probably correct: incidents just before the war suggested that Athens had not really renounced expansion, while Sparta had recovered and was ready to proclaim a crusade to liberate Greece from Athenian tyranny. But Spartan invasion and devastation were inadequate weapons against Athens, supplied with corn from overseas, and the cities of the empire were not eager enough for liberation. Fighting in the northwest, which could never be decisive, went in Athens' favour. Pylos on the Messenian coast, taken in 425, served as a refuge for fugitive helots, and Spartiate prisoners captured there caused Sparta great anxiety. But in 424 Athens was defeated near Delium by the Boeotians, and the success of the enterprising Spartan general Brasidas in the north gave the Spartans something to bargain with, so in 421 they gave up their crusade and signed the compromise peace of Nicias.

Several Spartan allies refused to sign this peace, which was never fully effective. In 418 Sparta actually fought Athens and allies at Mantinea, where the Spartan victory restored their position inside their own league, and in 414 Athens formally broke the treaty by raiding Laconian territory. The Spartans, resuming open war, fortified a permanent post at Decelea in Attica. The loss of Athens' expedition to Sicily (413) gave a fresh turn: Sparta, hesitantly at first, crossed the Aegean to provoke revolt in Asia Minor, where the remainder of the war was mainly fought to sever or protect Athens' vital access through the Hellespont to the grain of south Russia. The problem of maintaining campaigns at a distance had been partly solved by the use of detachments of allied troops and freed helots under officers called harmosts. In spite of Athenian victories at Cyzicus (410) and Arginusae (406), Lysander finally gained control of the Hellespont at Aegospotami (405) and Athens was starved into surrender (404). But the fleet which won the war was maintained only with Persian subsidies, notably those of Cyrus the younger to Lysander from 407 onward, and Persia's price was the surrender of the Greek cities of Asia Minor.

Spartan Empire.—Lysander (*q.v.*) aimed at a tightly controlled empire, and had secured political control of many cities through committees of ten (decarchies) of his personal adherents; and Athens was governed by "the Thirty" with a Spartan garrison. But jealousy of Lysander's power and distrust of his methods grew at Sparta. The turning point came with Thrasybulus' democratic rebellion at Athens, and King Pausanias was allowed to mediate a settlement by which democracy was restored (403): on his return to Sparta he was put on trial, but Lysander lost this trial of strength, and his decarchies were abolished. Sparta's prestige remained enormous, but Spartan troops and harmosts could not be everywhere.

In 401 Cyrus revolted against his brother Artaxerxes II with some Spartan help. When he was killed and the satrap Tissaphernes began to reconquer the coast of Asia Minor for Persia, the Greek cities there obtained Spartan help in a series of inconclusive campaigns, including those of Agesilaus II (*q.v.*) in 396 and 395. Meanwhile Sparta's continental ambitions in central Greece provoked Thebes to form a coalition with Athens, Argos

and Corinth against Sparta. They were defeated in 394 near Corinth, and again by Agesilaus' returning army at Coronea in Boeotia, but the destruction of the Spartan navy at Cnidus, by the Athenian Conon with a largely Persian fleet, largely compensated this. Sporadic land fighting went on around Corinth, and Thrasybulus in 389 recovered much of Athens' naval power. Thereafter Sparta and Persia rediscovered their common interest: Antalcidas with Persian and Syracusan help gained control of the Hellespont, thus paralyzing Athens, and imposed the king's peace or peace of Antalcidas (spring 386) which assigned all Asia Minor to Persia and proclaimed the autonomy of all other Greek states.

Sparta, led by Agesilaus, made ruthless use of this peace to dissolve the Boeotian league and any other combination thought dangerous. The seizure of the citadel of Thebes in 382 marked the height of Spartan power; but Thebes recovered its independence in winter 379, and an unsuccessful Spartan attempt to surprise the Piraeus alienated Athens, whose Second Confederacy spread widely, defeating the Spartan navy at Naxos. But the war exhausted both Sparta and Athens; peace was signed in 375/374 but immediately broken; at the next conference, in 371, Thebes refused to recognize the independence of the other cities of Boeotia, and when King Cleombrotus tried to impose this by force the Spartans were disastrously defeated at Leuctra (July 371).

Leuctra ended Sparta's domination. Impressive as it looked, it was never fully effective without Persian help, especially against Athens, and its effects were wholly negative. Spartan institutions, however much admired by theorists, were not a model that could be copied in an increasingly democratic Greece; and Sparta's great prestige could not suppress the resentment caused by Spartan interference. Greece as a whole was appreciably weaker since the 5th century.

Decline.—Epaminondas' liberation of Messenia (winter 370/369) cut off nearly half Sparta's resources, but Spartan power was not quite broken and Thebes could not dominate the Peloponnese: the Theban victory at Mantinea (362), marred by Epaminondas' death, only increased the confusion. Sparta held aloof from peace conferences, refusing to recognize the independence of Messenia, while some of the kings capitalized their military skill as mercenary leaders abroad. The Spartans took no part in resistance to Philip of Macedonia: Agis III led an anti-Macedonian movement while Alexander was conquering Persia, but was defeated and killed by Antipater at Megalopolis (331). Toward the end of the 4th century the city, hitherto proudly unwalled, was partly fortified; Areus I, who showed some military energy but was killed before Corinth (*c.* 265) during the Chremonidean War, struck coins in his own name; land had for some time been fully alienable and was falling steadily into fewer hands, but there was less of it since the loss of Messenia, and other territory was transferred to Sparta's neighbours by Philip (338) and later by Antigonus Gonatas. The pattern of Spartan life was changing.

Agis IV by peaceful agitation in 244, and Cleomenes III by force in 227, attempted to restore the old order. For details *see* AGIS; CLEOMENES: the basic plan was to cancel debts, redistribute land on the system ascribed to Lycurgus, bring up the numbers of the citizen population by admitting perioeci and others, and reestablish the ancient discipline. To the Hellenistic world, where the propertied classes had a firm grip on city politics, this was dangerous social revolution. Agis was soon suppressed. Cleomenes, more effective in his seizure of power, so alarmed the Achaean league by his military achievements and ambitions that Aratus (*q.v.*) of Sicyon reversed the policy of years and called in the Macedonian king Antigonus Doson; Cleomenes was defeated at Sellasia in 222, and died soon after in Egypt. The reforms were cancelled, but trouble continued. The Achaean leader Philopoemen defeated and killed a "tyrant," Machanidas, but the still more radical Nabis (*q.v.*) achieved some power and was partly tolerated by Rome till his assassination. Philopoemen then captured Sparta (188) and abolished the remains of the Lycurgan constitution: but many problems remained, especially the numerous exiles left over from this period of trouble, and Spartan discontents served as some excuse for Rome's war on the Achaeans (146).

Roman Sparta.—After Achaea became a Roman province, Sparta, though technically a free city, had no further individual history. Much territory had been lost, many of the perioecic cities being now detached in an independent league, and Sparta was wholly cut off from the sea: but under the wealthy citizen Gaius Julius Eurycles it took Augustus' side in the Roman civil wars and was rewarded with an outlet at Cardamyle (Kardhamili) on the Messenian gulf. Some picturesque features of the Lycurgan training were retained for the young—the flogging ordeal at the temple of Artemis Orthia, suitably brutalized, proved a tourist attraction —but their elders led the ordinary life of Roman provincials.

Medieval Sparta.—Sparta suffered severely during the invasion of Greece by the Visigoth Alaric in A.D. 395-396, and from subsequent invaders. Nevertheless, it remained a prosperous town and bishopric, often known as Lacedaemonia under the Byzantine empire. On the establishment of the Latin empire in Constantinople in 1204, the bulk of the Peloponnese became the Frankish principality of Achaea under the Villehardouin family, who built a new fortress and city named Mistra on a spur of Taygetus near Sparta. Michael Palaeologus recovered Mistra for the Byzantine empire as part of the ransom of William Villehardouin, captured at the battle of Pelagonia in 1259; thereafter it was the capital of the despotate of the Morea (*i.e.*, the Peloponnese), with a brilliant life of about two centuries (*see* MISTRA). From 1460 it was Turkish, with a Venetian interval from 1687 to 1715.

Modern Sparta.—The existing town (modern Gr. SPARTI) was built on the ancient site in 1834, after the establishment of Greek independence, and is the capital of the *nomos* (department) of Lakonia. Pop. (1961) 10,412.

SPARTACUS, leader in the Gladiatorial War against Rome (73–71 B.C.), was a Thracian by birth. He served in the Roman army but seems to have deserted and been sold as a slave. With about 70 fellow gladiators, he broke out of a training school at Capua and took refuge on Mt. Vesuvius (73 B.C.), where they were joined by other runaway slaves. They defeated two Roman forces in succession, overran most of southern Italy, and ultimately were several thousand strong. Spartacus defeated both consuls of 72 and fought his way successfully toward the Alps, intending his army to disperse to their homes. But the men refused to leave Italy, and he returned to Lucania, hoping to cross to Sicily. He was thwarted by the new Roman commander, M. Licinius Crassus, who had eight legions. Spartacus' army divided; the Gauls and Germans were defeated first, and he himself ultimately fell fighting in a pitched battle (71). Pompey's army met and killed many slaves who escaped northward, and 6,000 prisoners were crucified along the Appian Way by Crassus.

Spartacus was both competent and, apparently, humane, though his name inspired terror throughout Italy. It would be a mistake to call his revolt an attempt at revolution. Nevertheless, he has become the patron saint of revolutionaries, and from Adam Weishaupt in the late 18th century (*see* ILLUMINATI) to the present day the pseudonym "Spartacus" has covered many such; the most important were Karl Liebknecht, Rosa Luxemburg (*qq.v.*), and the other members of the German *Spartakusbund* of 1916–19. The theme of the slave rising has also been attractive to writers of fiction—as Arthur Koestler, *The Gladiators* (1939).

SPARTANBURG, a city in the piedmont section of South Carolina, U.S., the seat of Spartanburg county, is in the foothills of the Blue Ridge mountains, 32 mi. N.E. of Greenville. The name of the city and county commemorate the Spartan regiment

of South Carolina militia which fought in the American Revolution. Established first as a courthouse village in 1785, the town was in an area noted prior to 1860 for iron works, cotton planting and a few cotton mills. Nearby resorts at mineral springs drew a clientele from the entire state. After 1865 growth was accelerated by the intersection of three major rail lines at Spartanburg. By 1900 a number of cotton mills had been established on nearby streams. The trend to manufacturing continued in the 20th century; less than 12% of the county labour force is employed in agriculture and about 45% in manufacturing. Textile mills dominate county industry, which also includes bathroom fixtures, electrical equipment, food products, textile machinery, wearing apparel and chemical products. With the decline of cotton farming, farmers in the Spartanburg area turned to vegetable and peach production. The city was incorporated in 1831 and has a council-manager form of government in effect since 1947.

Spartanburg has a symphony orchestra, a civic band and a public-school symphony. It is the site of Converse college, a private college for women, founded in 1889; Wofford college, Methodist, for men, founded in 1854; Spartanburg Junior college, a coeducational Methodist institution, founded in 1911; and the South Carolina School for the Deaf and Blind (1849). Located near the city is Croft State park. The nearby mountains offer many recreational opportunities.

The population of Spartanburg is about 67% native-born white and 32% Negro. For comparative population figures *see* table in SOUTH CAROLINA: *Population*. (L. P. J.)

SPARTINA, a genus of grasses, most of whose seven or eight species are North American and as a group are commonly called cord, salt, or marsh grass. Salt meadow grass (*S. patens*) and smooth cord grass (*S. alterniflora*) are common on the salt marshes of New England. In Europe *S. stricta* occurs on the salt flats of southeast England, France, Portugal, and the Adriatic. *S. alterniflora* has been known at Southampton since 1829; it was probably introduced by shipping from America.

The genus is remarkable for the sudden appearance of a new distinct form at Southampton in 1870, *Spartina townsendi*. This tall-growing and robust form spread widely on the soft tidal muds of both sides of the English Channel. *Spartina townsendi* is exceptional in colonizing soft mud previously bare, for the vigour of its spread, and for its power of holding silt and raising the level of the mud. It is probably a hybrid between *S. stricta* and *S. alterniflora*. *Spartina spartinae*, gulf cord grass, native to the southern coastal plain of the U.S., produces wiry culms used, in combination with broomcorn, in the manufacture of household brooms and brushes. (F. W. O.)

SPASM: *see* CRAMP.

SPEAKER. Originally the name given to the presiding officer of the English house of commons, "speaker" has been adopted by many legislatures which have based their procedure on that of the British parliament. The office of speaker exists throughout the Commonwealth, but there are usually modifications of the British pattern: for example, in Australia, Canada and New Zealand the office is regarded as the privilege of the party in power and the occupant of the chair changes with the government. The office of speaker in the United States house of representatives is described below.

GREAT BRITAIN

Functions and Powers.—The speaker is the mouthpiece or representative of the house of commons in its relations with the crown, the house of lords and bodies or persons outside parliament. This function is largely confined to formal or ceremonial occasions. The speaker's main tasks are to preside over debates (except when the house is in committee), to enforce the observance of all rules for preserving order and to advise the house in its proceedings (for the presiding officer of the house of lords, *see* LORD HIGH CHANCELLOR). Conscious endeavour over the last 150 years has succeeded in making the office the objective embodiment of the rules and laws of the house, freeing it from any suspicion of partisanship. The speaker rules on points of order as they arise in debate and such rulings constitute precedents by which subsequent speakers are guided. He decides whether a proposal for an emergency debate should have precedence over the business already set down, and whether a prima facie case has been made out in complaints of breaches of privilege. He has the power to select amendments and to accept or reject a motion for the closure of debate. He can check irrelevance or repetition. Disorderly conduct can usually be restrained by a simple call to order; the speaker can direct the withdrawal of offensive expressions, or, in serious cases, "name" a member, which leads to immediate suspension from the house. If general disorder arises the speaker may either suspend the sitting for a period or adjourn the house at once without putting the question. The calling of members to speak in debate is entirely in the hands of the speaker, and his main concern is to ensure that a variety of points of view is heard. In addition to his duties in the chair the speaker controls much of the machinery of the house. His department includes the library of the house, and he is responsible, through an editor whom he appoints, for the production of the official report of debates (*Hansard*). He is also the chairman of the boundary commissions which review parliamentary constituencies, and from time to time he is called on to preside over conferences on electoral reform.

Rules, custom, ceremonial and deliberate policy combine to give the speaker, once elected, great authority. He is elected for a whole parliament (normally of about four or five years duration) and by custom dating back to 1835 is re-elected for as long as he wishes, no matter what changes of government may occur. The usual tenure of office is about 10 or 15 years. The house of commons' mace is carried before him on his daily procession to the house at the beginning of its proceedings. He is robed in a gown and full-bottomed wig; members bow to the chair on entering and leaving the chamber; all speeches are addressed to him; and when he rises to his feet all members must resume their seats and hear him in silence. The speaker's actions or rulings may not be criticized incidentally in the course of debate but only on a substantive motion, and such motions are rare. The speaker receives an annual salary of £5,000, which is charged on the consolidated fund and not voted annually, and in addition the annual allowance for parliamentary expenses paid to all members of parliament; he has an imposing official residence within the palace of Westminster. Formerly the first commoner in the land, the speaker since 1919 takes precedence immediately after the prime minister and lord president of the council. On retirement the speaker is offered a viscountcy and is voted a pension of £4,000 a year for life.

As important as the speaker's authority is his impartiality. On election a speaker severs all his ties with political parties and clubs. He takes no part in debate and votes only in the event of a tie, and then only in accordance with rules which preclude an expression of opinion upon the merits of the question. A. W. Peel (speaker, 1884–95) summed up the position when he said: "I know how necessary it is for any man who aspires to fill that great office to lay aside all that is personal, all that is of party, all that savours of political predilection, and to subordinate everything to the great interests of the house at large." J. W. Lowther (speaker, 1905–21) quoted with approval the remark that the office of speaker "does not demand rare qualities. It demands common qualities in a rare degree." The qualities chiefly required are good temper, patience, tact, judgment, and dignity in voice and bearing. A spice of wit, which can dissolve a strained situation in a burst of laughter, is invaluable.

Election of the Speaker.—At the beginning of a new parliament the sovereign commands the house to elect a speaker. When a new speaker has to be chosen the government of the day makes every effort, by informal discussion with the opposition and all shades of back-bench opinion, to discover a candidate who will command general support. Contested elections for the speakership are rare—the last two contests being held in 1895 and 1951. On the latter occasion W. S. Morrison (speaker, 1951–59), a former minister from the Conservative side of the house, was opposed by members of the Labour party, who put forward Major James Milner, for many years chairman of ways and means and deputy

speaker, as their candidate. The Labour party had not, by the early 1960s, provided the house with a speaker, and the feeling that it should be enabled to do so was widespread within the party in 1951, and again in 1959 when Morrison retired. Although the election of Sir Harry Hylton-Foster in 1959 was not contested by the Labour party, strong dissatisfaction was expressed at the inadequacy of the consultations that preceded his being put forward for the office. Upon his death in 1965, for the first time, a Labour member, Horace King, was elected speaker.

Once elected, the speaker is not normally opposed in his constituency by official party candidates at general elections. Since 1895 such contests have only occurred in 1935 and 1945, though unofficial candidates opposed the speaker in 1950 and 1955. If there is a contest the speaker refrains from any party political campaigning. It has been suggested, in order to spare the speaker any possibility of a contested election and to prevent his constituents being, in effect, disfranchised, that his constituency should be authorized to elect two members, that a fictitious constituency should be created, or that he should be enabled to sit in parliament without a constituency. However, a select committee of the house that reported on the matter in 1939 recommended that no change be made.

History of the Office.—Although the office can be traced back to 1258, when Simon de Montfort presided over the "Mad" parliament at Oxford, the first speaker to be so designated and the first known to have been chosen by the house of commons was Sir Thomas Hungerford, elected to the chair in 1377. Since that date, every parliament has elected its speaker. Although the choice of speaker was strongly influenced by the crown in the medieval period, several holders of the office showed considerable independence. A number of the early speakers met violent deaths, and the position of the speaker, between a strong king and a house concerned to increase its own power, could be an unenviable one. The custom whereby a newly elected speaker shows reluctance to accept office dates from this period. By 1642, after the constitutional struggle between Charles I and parliament, it was established that the first duty of the speaker was to the house, and when the king came to arrest five members, Speaker Lenthall replied to his questions with the memorable words: "May it please your majesty, I have neither eyes to see nor tongue to speak in this place, but as the house is pleased to direct me, whose servant I am here."

Since 1679, when Charles II refused to approve the re-election of Sir Edward Seymour, but failed to secure the election of his own nominee, royal approval of the commons' choice has been a formality, and by the end of the 17th century the speaker's independence of the crown was an established principle. In the 18th century dependence of the speaker on the crown threatened to be replaced by dependence on party. However, Arthur Onslow (speaker, 1728–61) raised the conception of the office to its present level by his resolute independence of all parties and his complete impartiality. His immediate successors failed to maintain his standards and once again the speakership was regarded as in the gift of the party in power, and few speakers took any pains to stand aside from politics. William Grenville, Pitt's nominee, was elected to the chair in 1789 when less than 30 years old, remained speaker for only five months, and later became home secretary and prime minister. Henry Addington, (afterward Viscount Sidmouth, speaker, 1789–1801), stepped straight from the chair to the premiership. However, during the 19th century the firm tradition of an independent and nonpartisan speaker was built up, a process especially associated with Charles Shaw-Lefevre's tenure of the office (1839–57). (H. J. Pa.)

UNITED STATES

The United States constitution (art. 1, sec. 2) provides that "the House of Representatives shall chuse their Speaker and other Officers . . ." In creating this office its authors had in mind the speaker in the colonial assemblies who had been both a presiding officer and a political leader. Early expectations were later realized, for U.S. speakers after 1789 were both parliamentary and political personalities.

The speaker of the house holds an office of dignity and honour, of great power and influence. Usage dictates that he shall always be a member of the house, and as such the constitution requires him to be seven years a citizen and at least 25 years of age. Candidates for the office are nominated by party caucuses prior to the convening of each congress and the speaker is customarily elected by the house on the opening day, barring a protracted contest. Competition for the place has often been keen and the final choice is influenced by knowledge of parliamentary procedure, previous legislative experience, sectional claims, private interests, personal qualities and political considerations.

History of Office.—From the beginning the speakership has generally been held by men with previous experience in state legislatures; many of the speakers of the house of representatives have been men with experience as speakers of their state legislative bodies. Fewer than one-fifth of the speakers who served during the first 170 years of the constitution's history were without any prior state legislative experience, and of these none held the office prior to at least his fourth term in the national legislature. Only three speakers were elected to the office in their first term in the house of representatives: Frederick A. C. Muhlenberg, the first speaker, who had been speaker of the Pennsylvania house and a delegate to the constitutional convention; Henry Clay, who had served several terms in the Kentucky legislature as member and speaker and had been a U.S. senator; and William Pennington, who had once served in the New Jersey assembly. With the exception of these three, every speaker had had prior service in congress, ranging from 1 to 16 terms.

Many famous men have served as speaker of the house—James K. Polk, Schuyler Colfax, James G. Blaine, Thomas B. Reed, Joseph G. Cannon, Champ Clark, Frederick H. Gillett, Nicholas Longworth and Sam Rayburn. Rayburn set a record for the longest service—nine terms, including two half-terms. After Rayburn the next longest term of service as speaker was that of Clay—six terms, five of them consecutive. Andrew Stevenson, Cannon and Clark served four terms each; Nathaniel Macon, Colfax, Blaine, Samuel J. Randall, John G. Carlisle, Reed, Gillett, Longworth and William B. Bankhead each had three terms in the chair.

More than one-third of the speakers have come from the south, about twice as many as from any other part of the country. Southern influence predominated in the organization of the Democratic party, for the "solid south" was overwhelmingly Democratic after the Civil War and repeatedly re-elected the same congressmen. Southern members thus acquired seniority and power in party councils and most Democratic speakers from 1865 to 1961 were southerners. In 1962 John W. McCormack, Democrat of Massachusetts, was elected speaker to succeed Rayburn. (For a list of speakers *see* UNITED STATES [OF AMERICA]: *Table VI.*)

Powers and Duties.—The parliamentary powers and duties of the speaker stem from four sources: the constitution and laws of the United States, the rules of the house, previous decisions of the chair and general parliamentary law. He presides at sessions of the house and opens and closes its sittings, acts as its spokesman and representative, and authenticates documents, announces the order of business, puts questions and announces the vote.

He also decides questions of order, prevents obstruction of house business, refers bills and reports to the proper committees or calendars, chooses speakers pro tempore and appoints the chairmen of committees of the whole. These duties he performs impartially like the speaker of the house of commons, as evidenced by the fact that his decisions are rarely appealed; however, he also enjoys the privileges of an ordinary member of the house and may vote and take part in debate on the floor.

Prior to 1910 the speaker also possessed important political powers. He appointed, deposed and demoted the chairmen and members of committees; he served as chairman of the committee on rules, which enabled him to control the business of the house; and he recognized or refused to recognize members claiming the floor. These powers, gradually evolved by strong speakers like Reed and Cannon, reached a peak of perfection and omnipotence during the latter's regime. So dictatorial and despotic, indeed,

did Speaker Cannon become that the house rebelled, and in March 1910 a coalition of Democrats and insurgent Republicans succeeded in drastically curtailing his powers. They removed him from the rules committee, deprived him of the power to appoint standing committees and restricted his right of recognition.

Although the speaker was removed from the committee on rules in 1910, he continued to sit on the unofficial steering committee that meets in his office and determines party strategy. Though he no longer has the power to appoint standing committees, he retains the power of appointing house conferees, the chairman of the committee of the whole and select committees. His power of recognition was reduced, but he still has a discretionary power of recognition over motions to suspend the rules and on days other than consent calendar days.

Place in Political System.—The Presidential Succession act of 1947 ranked the speaker of the house first in line of succession in case of the death or disability of both the president and vice-president. Relations between speakers and presidents have fluctuated between rivalry and harmony through the years. During periods of congressional supremacy the chair has overshadowed the White House, while popular-leader presidents have dominated congress. Despite the reduction in his powers, the speaker continues to be at once the presiding officer and titular leader of his party in the lower chamber, a private member and the most influential man in the house of representatives. SPEARMAN, CHARLES EDWARD (1863–1945), British psychologist whose chief contributions dealt with the theory of intelligence and cognition, was born in London on Sept. 10, 1863. As an officer in the British Army, he served in the Burmese war of 1885 and in the South African War, and did not obtain his doctorate in psychology at Leipzig until he was 40. His earliest researches were concerned with the improvement of psychophysical methods, especially as applied to visual perception. On returning to England, he joined a group at Oxford who at William McDougall's suggestion were applying Karl Pearson's correlational techniques to develop tests of intelligence for Francis Galton's projected surveys in British schools. His first results were reported in "General Intelligence Objectively Determined and Measured" (1904). Galton had maintained that intellectual processes depended both on a "general ability" and on a number of "special abilities"; Spearman sought, by simplifying Pearson's methods, to show that "general ability" alone sufficed, but later modified this extreme position; his animated controversies with Pearson and other critics led to a valuable series of factorial researches from both sides. He died in London on Sept. 17, 1945.

Spearman's books include *The Nature of Intelligence and the Principles of Cognition,* 2nd ed. (1927); *The Abilities of Man: Their Nature and Measurement* (1927); and, jointly with L. Wynn Jones, *Human Ability* (1950). (Cy. B.)

SPECIES. The nature of species is a question of considerable importance in general biology. The term is regularly employed as a taxonomic unit, or taxon, in systematic botany, zoology, and mineralogy, but despite its wide use its definition remains elusive. The word "species" is the Latin equivalent of the Greek *eidos, idea* ("class") and originally meant primarily shape or visible form but was extended to cover the sensible character of things generally, and also the intelligible.

PHILOSOPHY

As intelligible character, *eidos* or species was the common essence of individuals or instances of the same kind. As such, it was an object of thought, not of sense; universal, not individual; and, unlike its instances, exempt from generation and decay. Its relation to its instances (which may be compared with that of a law to the events exemplifying it) was a subject of dispute both in Greek and scholastic philosophy. There were also disputes about the relation of species to their common genus, of which they are determinations, and to the properties connected and accidents conjoined with their specific nature in individuals of a species. In particular it was disputed whether species and genera were anything real independently of our minds, or only common names, or else notions of ours, the products of man's classifying activity. A settlement of these questions is not necessary to the work of the systematic biologist, but they must be faced if it is really to be understood what is meant by the evolution of species; for this evolution is a process of which no persisting material thing is the subject. (H. W. B. J.)

BIOLOGY

History.—The concept of species as a kind of animal or plant is an old one in biological literature. Aristotle (384–322 B.C.) used the term for groups of organisms with common characters, and these in turn he subdivided into more species. John Ray (1627–1705) is usually given the credit for using the term for groups with mutual fertility. Carl von Linné (*see* Linnaeus, Carolus; 1707–78) established a system of binomial nomenclature universally used in the 20th-century. Each organism was classified as a member of a species, and each species was included in a higher taxonomic group, the genus. The genera were also classified in still higher taxonomic categories, but the binomial name consisted of the names of the genus and the species together.

International congresses of botany and zoology, respectively, formulate, administer, and interpret the international rules of botanical and zoological nomenclature. The basic principle used for natural classification is homology (*q.v.*). In early modern times homology was a vague concept applied roughly to apparent similarities of structure. During the 20th century, genetics, embryology, ecology, and evolutionary analysis came to place a firm scientific foundation under the concept of homology, with consequent clarification, correction, and verification of systematic biology.

Linnaeus first believed in the fixity of species but later in his life suggested that the genus constituted the ancestral species at the time of creation and that derived species subsequently multiplied by means of hybrid generation or intercrossing between species. During the 19th century, particularly through the work of Lamarck (1744–1829) and Charles Darwin (1809–82), the theory of the evolution of species was accepted by the large majority of biologists (*see* Evolution, Organic).

The importance of isolation in the origin of species was emphasized by M. Wagner (1813–87) and J. T. Gulick (1832–1923). Modern genetic theory, initiated by Mendel (1822–84) by means of his investigations of domestic varieties of plants, was applied to both plants and animals in the early 20th century. Mendelian genetics of individuals led gradually to the establishment of the science of population genetics during the third and fourth decades of the 20th century. Population genetics substantiated the concept of the biological species and greatly improved the understanding of evolutionary processes.

Attempts at Definition.—The species is recognized as a prime biological unit with objective criteria. More than 1,000,000 species of animals and more than 300,000 species of plants had been named by mid-20th century; probably at least twice this number will ultimately be recognized when the knowledge of the world faunas and floras approaches completion.

There are almost as many definitions of "species" as there are biologists who have attempted to condense the major aspects of the concept. A brief definition that includes the most generally recognized criteria of the biological species was given by A. E. Emerson in 1945: a species is an evolved or evolving, genetically distinctive, reproductively isolated natural population. All of these attributes are necessary, and no others would seem to be essential. Each attribute is discussed separately in the following paragraphs.

Since the establishment of the principle of evolutionary change, species have been considered to be dynamic entities, hardly fixed or static, as was once believed. Evolutionary characterization is therefore necessary in the definition. Demarcation of species is sometimes somewhat arbitrary when transitional stages are encountered; however, true evolutionary gradations are not often found, so that ancient continuities are seldom observable between living species, and the paleontological record seldom bridges the gaps between species categories. Although nomenclature is easier when the ancient continuities are unknown, cases in which intergradations between species can be directly observed offer an opportunity for a more exacting study of the processes of speciation, and analytical biologists seek such material for investigation. Also, the early stages in species divergence that have not progressed to the point of complete species division enable the scientists to analyze the dynamic factors more exactly and are consequently sought.

Genetic distinction seems to be the common denominator for all valid qualitative or quantitative species characters, including cytological, physiological, embryological, ethological, ecological, and morphological characters. Taxonomists, of course, seldom can experimentally investigate the genetics of the species they study and must rely upon structural or colour indications of genetic relationship. Anatomy and pigmentation often are sensitive to small genetic influences that are not easily detected by other techniques of observation. Heredity may be inferred through demonstrated germinal continuity in populations and through the experimentally established basis of similar characters in investigated organisms. Hybrids and intergrading populations give some genetic information. If striking structural characters are not correlated with genetic distinctions of reproductively isolated natural populations, the taxonomist usually does not use them for species separation and will correct errors that have been committed in ignorance of the genetic implications. For example, structural changes produced by various conditions at the time of growth, by differences in stages of development, by sexual dimorphism, by castes of social insects, and by various types of polymorphism do not meet the criteria of genetic distinction and reproductive isolation. On the other hand, slight genetic distinction of natural populations that are reproductively isolated may be used for species separation, while gross genetic differences of individuals or of only partially isolated populations are not valid for species distinction.

Reproductive isolation, or lack of gene flow between populations, may result from chronological separation, spatial separation, topographical or geographical barriers to dispersal, habitat or ecological restrictions, cyclic differences in breeding periods, mechanical inability to crossbreed, psychological or ethological barriers to interbreeding, physiological barriers to fertilization, genetic unbalance preventing fusion, inviability of hybrids, hybrid sterility, and selective elimination of hybrids. Regardless of the exact type of isolation or the combination of isolating factors, anything that prevents genes from moving from one population to another has profound evolutionary consequences. Reproductive isolation is the dividing factor in the branching of the phylogenetic tree, and the two populations thus deprived of gene exchange will tend to drift apart through changes in gene incidence and gene or chromosome mutation. Because of its effect upon inbreeding, reproductive isolation also influences gene and character fixation. As most taxonomic characters are the result of complex genetic patterns rather than single genes or chromosomes, the consolidation of these patterns and their transmission as systems becomes a necessity for further adaptive evolution. Fixation of complex genetic patterns is a primary consequence of reproductive isolation. Reproductive isolation may take place gradually and give rise to many subdivisions of the species population before speciation is completed. Theoretically the point of species origin is the moment that genetically distinctive natural populations cease gene exchange. Practically it may not be possible to recognize this point in instances of contemporary speciation. However, the large majority of valid species have been isolated for thousands or millions of years, so that it is a rare case that presents difficulties when an abundance of evidence is accumulated.

An important group of biologists, including Theodosius Dobzhansky (1951) and E. Mayr (1942), excluded extrinsic barriers to gene flow (geographical or ecological) in their definitions of reproductive isolation as applied to species and confined the concept to examples separated by intrinsic barriers (psychological, genetic, and physiological). They did not give full species rank to genetically divergent natural populations completely lacking gene exchange if such populations have not lost their potential ability to interbreed when the extrinsic barriers are removed. Inasmuch as it is often impossible to judge the potentialities of interbreeding under natural conditions, these biologists had to rely upon a rough correlation between interbreeding potentialities and degrees of taxonomic divergence. When two related species occupy the same territory (sympatric species) and no intergrades occur between them, biologists may assume an intrinsic barrier to gene flow. Such an assumption is much less warranted in the cases of closely related but geographically separated distinctive populations (allopatric species), however; and there is a resulting confusion of taxonomic status of numerous groups. One school of taxonomists may refer certain populations to full species rank, while the other school will treat the same populations as subspecies.

If reproductive isolation includes the extrinsic barriers to gene flow, it is possible that species that have not evolved intrinsic barriers may ultimately interbreed when there is an occasional breakdown of temporary extrinsic barriers. The hybrid origin of a species from two preexisting species is thereby a possibility. The school of biologists that confines reproductive isolation between species to intrinsic prevention of gene flow does not recognize full species status for the extrinsically isolated populations and would not allow for the possibility of hybrid origin of species except in special cases in which intrinsic barriers are also broken down (allopolyploidy in plants). In spite of these differences of opinion of the exact definition of reproductive isolation, with consequent confusion over the taxonomic status of some natural populations, the large majority of plant and animal species prove to be intrinsically isolated. Therefore, there is common agreement among biologists concerning most species limitations, together with the criteria for the recognition of the species category.

The final characterization of the species is that it constitutes a natural population. The population is integrated by means of genetic continuity through reproduction; it may also be integrated through sexual reproduction and various other adaptations for attraction and interaction between individuals of the same species. The species population is often subdivided into many subpopulations, but the larger species population is a real entity with a definite boundary. Differences in fundamental biological interactions occur *within* the species population, in contrast with the biological interactions *between* species populations. The species is generally conceived to result from natural evolution. Artificial populations compounded by man through domestication or for scientific investigation are not given species rank even when they are genetically distinctive and reproductively isolated populations. Under natural conditions such man-produced populations would seldom maintain their genetic distinctiveness, if they were able to survive at all! The domestic dog is classified as a full species (*Canis familiaris*), but the separate breeds are not. Corn (*Zea mays*) is a full species; selectively bred types of sweet corn are not.

Related Categories.—Numerous infraspecies categories relate to variations in the qualitative or quantitative attributes of the species. Each term places emphasis upon particular aspects of the species concept. Some of the terms are defined below and are useful in the study of speciation mechanisms.

Sexual Species.—This term is used for species that possess sexual adaptations and interfertility among the component individuals. Sexual recombination of genetic elements greatly increases genetic variability. Many definitions of species confine the concept to the sexually interbreeding population.

Asexual Species.—These are species that have never evolved sexual fusion or have secondarily lost the ability to intercross. All reproduction is confined to division, parthenogenesis, apomixis, or vegetative reproduction. This species category would include

the primary asexual bacteria and many single-celled organisms and would also include the secondarily asexual parthenogenetic animals and apomictic plants. In asexual organisms reproductive isolation between individuals of the same generation is absolute, and genetic continuity is only through descent. In some instances taxonomic distinction is maintained for periods comparable to the maintenance of taxonomic pattern in sexual species (species of flagellate protozoans inhabiting the hind gut of termites). In other instances taxonomic distinction may vary over short periods of time, and the species category is difficult to apply (virulent and nonvirulent strains of viruses and nutritive strains of bacteria).

Subspecies.—A subdivision of a sexual species with all the attributes of the species except that reproductive isolation is partial rather than complete. Subspecies are given trinomial names by taxonomists and are recognized as constituting a valid category in the international rules of nomenclature. A species subdivided into subspecies or races is called a polytypic species.

Race.—Race is not separated by definition from the subspecies. However, it is either used as a synonym for the subspecies category or is given a rank slightly below that of the subspecies, presumably because the degree of reproductive isolation is smaller than that separating the subspecies.

Deme.—A communal interbreeding population within a species either wholly or partially isolated from other demes. The term has little currency.

Supraspecies.—A collection of groups or subspecies that replace each other geographically or physiologically and in which the extremities only have evolved intrinsic isolation. Connecting groups between the extremities interbreed and intergrade. There are several known cases among snakes, birds, and mammals in which intersterility occurs among some of the subspecies within the species.

Coenospecies.—The sum total of possible combinations of a genotype compound as seen particularly through cultivation under artificial conditions. The term has also been used to include groups of species separated only by extrinsic barriers to gene flow.

Ecospecies.—The species as realized in nature under the limitations imposed by the natural environment. It emphasizes the limitations of potential variation produced by natural selection.

Biotype.—A population of individuals with identical genotypical constitution under similar conditions. Biotypes are usually limited to asexual species or to populations within a sexual species that result from asexual reproduction from a single individual. Parallel mutation may possibly account for some biotypes.

Clone.—A group descended from a single individual without sexual combination. The individuals are presumably genotypically identical or isogenic. The term overlaps somewhat with the biotype.

Lineage.—A racial complex of several lines of descent forming a meshed network of evolution within the species.

Variety.—The category for individuals or small groups of individuals that varied in a describable way from the typical individuals in the species. Varieties may be considered somewhat distinctive groups that fall within the range of species variation as a whole but do not necessarily have geographical or ecological correlations.

Cline.—A character gradient within a group—usually within a species. Numerous subdivisions of clines are named when there is a correlation with special factors. Ecoclines are correlated with ecological gradients. Geoclines are correlated with geographical gradients. Taxoclines are correlated with taxonomic gradations associated with hybridization. Chronoclines are correlated with time in paleontological sequences. Ontoclines are gradations in the appearance of characters during the life cycle of individuals.

Physiological Species or Races.—Species or subdivisions of a species that are recognized by physiological characters rather than structural characters. Genetic distinction is usually manifest in structural or anatomical characters, but gene patterns may effect physiological characters without producing sufficient anatomical effects to be recognized. The term "biological race" is essentially synonymous with "physiological race."

Incipient Species.—A diverging, partially isolated population that may become a species when isolation becomes complete.

SPECIFIC GRAVITY is a number expressing the relative density (mass per unit volume) of a substance; it is defined as the ratio of the density of the substance to that of a standard. The standard is usually taken to be water at 4° C (39.2° F); accordingly, if the specific gravity of a body at 4° C is less than 1, the body will float in water at that temperature; if it is greater than 1, the body will sink. Specific gravity and density refer to the same physical property (in the metre-kilogram-second system of units they have the same numerical value); it is a matter of convenience which one is used. *See* DENSITY; MECHANICS, FLUID: *Buoyancy;* HYDROMETER; JOLLY BALANCE; and also references under "Specific Gravity" in the Index.

SPECK, FRANK GOULDSMITH (1881–1950), U.S. anthropologist, an authority on Indian tribes of eastern North America, was born on Nov. 8, 1881, in Brooklyn, N.Y. He took his M.A. degree in 1905 at Columbia University under Franz Boas, and his Ph.D. at the University of Pennsylvania in 1908. In the same year he initiated a program of anthropological studies at the University of Pennsylvania, where he became professor in 1925 and continued teaching until his death. He did intensive field research among the Indians of the eastern United States and Canada, particularly the Algonkian and Iroquois. Within the communities he visited, Speck was welcomed as a friend and confidant. Vitally interested in linguistics, he mastered several Indian languages and, in a few instances, recorded some known only to a few remaining speakers. He published such important monographs as *Ethnology of the Yuchi Indians* (1909), *Naskapi, the Savage Hunters of the Labrador Peninsula* (1935) and *Penobscot Man: the Life History of a Forest Tribe in Maine* (1940). He discovered and described the territorial hunting system of the northeastern Algonkian tribes. Speck dealt authoritatively with a wide range of topics—technology and decorative art, social organization, folklore and music. One of his perennial interests was religion and ceremonialism. He also contributed to ethnobotany and ethnozoology. He died on Feb. 6, 1950, in Philadelphia, Pa.

See A. I. Hallowell, "Frank Gouldsmith Speck, 1881–1950," in *Amer. Anthrop.*, 53:67–87 (Jan.–March 1951), with a bibliography by J. Witthoft. (A. I. H.)

SPECTACLES: *see* EYEGLASSES.

SPECTROCHEMICAL ANALYSIS, in its broadest sense, comprises all methods of chemical analysis that depend upon the measurement of the wavelength and the intensity of spectrum lines or bands, and encompasses all frequencies in the electromagnetic spectrum. In its restricted and commoner usage two methods are implied: (1) ultraviolet and visible emission spectroscopy and (2) ultraviolet and visible absorption spectrophotometry. Both methods serve to characterize the qualitative and quantitative composition of matter.

Emission Spectrochemical Analysis.—In emission spectroscopy atoms are excited to higher electronic energy levels above their ground states by means of electrical discharges (arcs or sparks) or flames. Atoms of unknown identity in a specimen so excited emit light of characteristic frequencies when they return to lower energy states. These characteristic frequencies are separated into an ordered sequence (spectrum) by diffraction or refraction in a spectrograph for visual, photographic or photoelectric registration. The process therefore consists of three interdependent steps: (1) the vaporization and electronic excitation of atoms, (2) separation of the emitted light into its component frequencies and (3) measurement of the wavelength and intensity of selected frequencies.

Each chemical element possesses its unique and characteristic

collection of spectral frequencies, whose recognition in the spectrum of an unknown substance therefore provides unambiguous evidence of the presence of that element. Ordinarily emission spectrochemical analysis is applied to the qualitative and quantitative determination of metallic elements, but it is not restricted to them. The method is among the most sensitive of all analytical methods, a few milligrams of a solid sample usually sufficing for the detection of metallic elements present to the extent of only parts per million. Although a given element may provide many thousands of spectrum lines, depending upon its energy level system and its concentration in a sample, it is not necessary to identify each wavelength. Normally the identification of three prominent lines in the spectrum of a sample serves to ensure the presence of an element with high reliability, while the absence of one of its most sensitive lines certifies the absence of the element to the level of spectroscopic detection.

The physical state of the sample suitable for spectrographic analysis may vary widely. Metallic samples are usually fabricated into rods or disks for electrodes in an arc or spark discharge. Powders and nonconducting solids are conveniently placed in a crater formed in a rod-shaped carbon or graphite electrode of high purity for volatilization and excitation. Solutions, biological fluids and tissues are generally converted to dried inorganic residues before vaporization and excitation from graphite or metal electrodes.

Quantitative analysis by emission spectroscopy depends upon the fact that the quantity of light emitted in a given spectrum line is proportional to the number of atoms vaporized and excited. To establish the relationship between the concentration of an element and the quantity of light emitted in one of its spectrum lines, it is necessary to provide a series of standard samples in which the matrix composition is fixed, and the sought element varies in concentration in a known and graded manner from standard to standard. Semiquantitative analyses may then be carried out by visual comparison of the photographic density of a spectrum line in the unknown sample with the densities of the same line in the spectra produced from the standards. More refined quantitative analyses, precise to about 1% of the element concentration, may be made by measurement of the spectrum line densities with a microphotometer. Since it is exceedingly difficult to maintain constant excitation conditions during the excitation of a sample and to reproduce them from sample to sample, absolute measurements of spectrum line intensities are not made. Instead a relative method, called the internal standard method, is employed. Devised by W. Gerlach in 1925, the internal standard method relates the intensity of a spectrum line of the sought element to the intensity of a suitable spectrum line of an element whose concentration remains constant in all standards and unknown samples. Fluctuations in the excitation conditions then affect the intensity of the unknown and standard equally, and their intensity ratio is independent of the unavoidable variations in the excitation and photographic processes. Frequently, as in the analysis of nearly pure metals or alloys of definite composition, the internal standard line is chosen from among the spectrum lines furnished by the base element. When this is not feasible, it is often possible to add an internal standard element in equal concentration to standards and samples alike.

Although the emission spectrographic method has relied greatly upon photographic emulsions for the recording and measurement of spectrum lines, and continues to be useful, increasing use is being made of photoelectric methods for the direct measurement of spectrum line intensities. Particularly in routine metallurgical control analyses, in which speed and a large volume of determinations are of importance, direct-recording spectrometers are available. These instruments receive spectrum lines in electron photomultiplier tubes and record the analytical composition directly on digital counters or print the results on tape.

Absorption Spectrophotometry.—Quantitative analysis by absorption spectroscopy depends upon the fact that many substances characteristically absorb light of a given frequency or range of frequencies. Commonly in analysis the absorbing substance is an ion or molecule in unknown concentration in aqueous solution. Those frequencies of light are absorbed which electronically excite the molecule or ion to a higher energy level. The diminution in intensity of light passing through the solution is related to the length l of the light path and the concentration c of the absorbing species by the Beer-Lambert law:

$$I = I_0 \exp(-\epsilon c l)$$

In the Beer-Lambert law, I is the intensity of light transmitted by the solution; I_0 is the intensity of light transmitted by the solvent alone; and ϵ, the extinction coefficient, is a constant characteristic of the absorbing species. Many ions which alone do not absorb light strongly can be made to absorb strongly by causing them to form complex ions with other ions or molecules. The sensitivity and specificity of detection may often be greatly increased by appropriate selection of complexing agents.

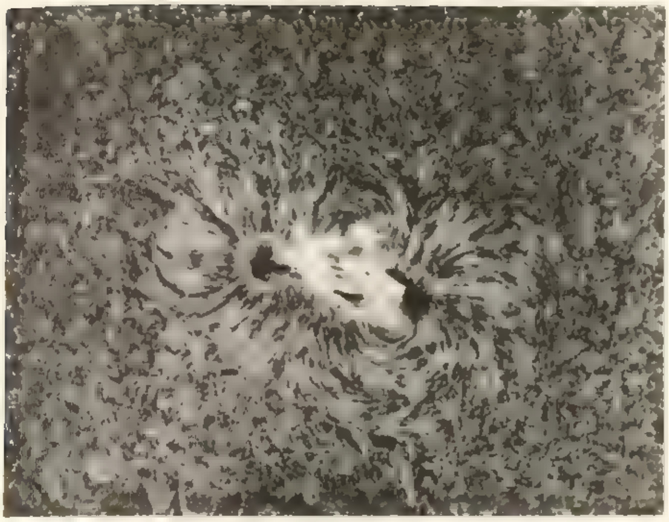
SPECTROHELIOGRAPH, an instrument that utilizes the spectrum for photographing the sun with monochromatic light. In its simplest form it consists of a spectrograph in the focal plane of which is a second slit that transmits monochromatic light to a photographic film. This slit may be set at any wave length in the spectrum, usually on a strong spectral line produced by some particular chemical element; *e.g.*, the K line of calcium or the Hα line of hydrogen. An image of the sun is formed by a telescope objective on the collimator (first) slit of the spectrograph, and the photographic film is mounted almost in contact with the second slit. In operation, the spectroheliograph is moved parallel to itself, admitting to the first slit light from all parts of the sun as the slit moves across the sun's image. Simultaneously the second slit is moving across the photographic film, building up an image of the sun with the monochromatic light transmitted by the slit. Thus the distribution of calcium or hydrogen clouds in the sun's atmosphere may be recorded. Such clouds are invisible to the eye and are not shown on a solar photograph taken in the usual way. Similar solar photographs can be obtained, however, without a spectrograph by using filters that transmit nearly monochromatic light.

The spectroheliograph, originally designed for photographing only the solar prominences at the sun's edge, disclosed in its first application by George Ellery Hale at the Kenwood observatory (Chicago, Ill., 1891) new, unexplored features of the sun's atmosphere. Photographs of the solar disk showed extensive luminous clouds (flocculi or plages) vastly greater in area than the sunspots around and above which such clouds are always found. These clouds may also appear where no spots are visible. Although in the lower, denser vapour the clouds appear bright, in the rarer vapour at high levels the light from below is absorbed, giving rise to dark clouds. The relatively dark clouds are the prominences that appear bright at the sun's edge.

At about the time that Hale was devising his spectroheliograph, H. Deslandres at the Paris observatory introduced a velocity spectrograph which permitted motion in the line of sight to be measured on photographs of the K (or H) line in successive sections of the sun. Such a series of photographs reveals the same features as shown on spectroheliograms.

The first photographs of the sun in hydrogen light were made with the spectroheliograph at the Yerkes observatory (Williams Bay, Wis.) in 1903 using the blue and violet spectral lines of hydrogen. Later, in 1908, at the Mt. Wilson observatory (near Pasadena, Calif.), when methods for making photographic emulsions sensitive to red light had been developed, the red hydrogen line (Hα) was used. The long dark flocculi (filaments) shown on high-level calcium spectroheliograms and identified as prominences projected against the surface of the sun are very conspicuous on spectroheliograms made in the centre of Hα.

In the high region of the sun's atmosphere over sunspots the distribution of the small dark flocculi shown by the hydrogen photographs suggests the operation of definite forces. Surround-



BY COURTESY OF THE MOUNT WILSON OBSERVATORY

HYDROGEN CLOUDS NEAR SUNSPOTS

Hydrogen clouds surrounding a large, magnetically bipolar group of sunspots, photographed at the Mt. Wilson observatory with the 13-ft. spectroheliograph using the red hydrogen line (Hα). The forms of such clouds resemble those of iron filings over a bipolar magnet or flow lines around double vortices rotating in opposite directions

ing large single isolated spots, these flocculi often form great vortices that resemble terrestrial cyclones or tornadoes. About 75% of these appear as huge spirals, clockwise in the southern hemisphere and counterclockwise in the northern. The detection of these vortices led, in 1908, to the discovery of magnetic fields in sunspots.

Spectrohelioscope.—The functions of the spectroheliograph and velocity spectrograph are combined in the spectrohelioscope, an instrument that renders visible to the eye many of the phenomena of the solar atmosphere photographed with the spectroheliograph and also permits their velocity in the line of sight to be measured. The principle of the spectrohelioscope was suggested by C. A. Young in 1870 and was used by him for observing prominences at the sun's limb. Hale, who revived and improved the instrument (1924), succeeded in observing with it the bright and dark hydrogen flocculi and in measuring their velocities.

Imagine a narrow slit, rapidly oscillating, between the eye and a telescopic image of the sun. Through persistence of vision, the image can be seen in white light. A spectroscope becomes a spectrohelioscope when placed in the optical path so that it transmits to the eye through a second slit only the light of the red hydrogen line. Instead of moving the slits, the sun's image may be moved. A method commonly employed is that of placing a rotating prism with a square cross section in the telescope beam in front of the first slit and viewing the second slit through another prism rotating at precisely the same rate as the first.

A "line shifter" consisting of a plane parallel-sided glass plate mounted behind the second slit displaces the spectral line toward the red or violet when rotated. The amount of rotation indicates the wave length of the light being utilized and the velocity of the observed features. In the spectroheliograph the displaced line would be off the slit, and the image of rapidly moving gas would not be recorded.

The spectrohelioscope affords a rapid means of detecting and studying many solar phenomena, since the entire disk and limb can be examined in less than a minute. These instruments have been widely used in the detection of flares that suddenly increase in brightness and then fade more gradually. Such flares are solar clouds and usually occur near sunspots. Flares affect the ionosphere directly, causing interference in radio transmission, and less directly in the production of aurora and geomagnetic storms.

SPECTROPHOTOMETRY is a subdivision of physics and chemistry which deals with the relative measurement of radiant energy (power) as a function of wavelength, frequency, or wave number. Thus, the radiant energy transmitted (reflected) by a body is compared with that transmitted (reflected) by some other system taken as a standard. Absorption spectroscopy and spectrometry are other terms often used synonymously.

Different types of modern instruments cover a wide range of wavelengths of the electromagnetic spectrum. Approximate limits of several spectral regions are: X ray, less than 1 to 100 angstroms (Å); ultraviolet, 10 to 400 millimicrons (mμ); visible, 400 to 700 mμ; infrared, 0.7 to more than 500 microns (μ); and microwave, 0.1 to 1,000 cm. The relationship among these units is given by

$$1\text{Å} = 0.1\text{m}\mu = 10^{-4}\mu = 10^{-8}\text{ cm}.$$

Two laws express the relationship of the absorption of radiant energy to the absorbing medium. According to Bouguer's law, each layer of equal thickness of the absorbing medium absorbs an equal fraction of the radiant energy traversing it. According to Beer's law, the absorptive capacity is directly proportional to the concentration of the solute in a solution. One expression of the combined laws is

$$\log_{10} P_0/P = \log_{10} 1/T = A = abc$$

in which P_0 and P are the radiant power (flux) transmitted by the standard and by the unknown, respectively; T is the transmittance which is equal to P/P_0; A is the absorbance; and a the absorptivity, b the thickness, and c the concentration of solute. Thickness and concentration are often expressed in centimetres and grams per litre, respectively. For a molar solution, the symbols ϵ and a_M are widely used for molar absorptivity. Deviations from Beer's law are common for solutions, but Bouguer's law is said to apply to all homogeneous systems.

Although spectrophotometers may vary widely in their spectrometric, geometric, and photometric designs, they consist essentially of (1) a source of radiant energy, (2) a monochromator, (3) a photometer, and (4) a detector for the unabsorbed radiant energy. An absorption cell holds the liquid or gas samples. With the majority of instruments a photometric value is obtained for each wavelength setting. For extensive scanning work, recording instruments greatly facilitate the accumulation of data. Most rapid of all is a model incorporating an oscillograph with attached camera for recording.

Occasionally monochromatic light sources are used, but generally continuous sources (for given regions) are employed. Examples of the latter are the hydrogen arc (ultraviolet), the incandescent tungsten filament (visible), and the Nernst glower (infrared). The monochromator isolates a narrow spectral band from a continuous source, and the photometer serves to measure P/P_0, or some related value, for this band. The detector varies from region to region, there being no universally usable means. Among those commonly used are photographic plates, photocells, thermopiles, and bolometers.

A curve coordinating photometric values with spectral positions is known as an absorption spectrum. Usually ordinates are T, A, log A, or log ϵ, and the common abscissas are wavelength, log wavelength, wave number, or frequency. Often only a value at a single wavelength is needed.

Ideally, the absorptivity a is a constant, characteristic of a given system. As such, it is comparable to a density or refractive index value. Unfortunately, because of lack of adequate control of instrumental and solution conditions, this ideal is not generally realized. Instrumental variables include spectral band width, cell thickness, stray radiant energy, and general operation of the instrument. Various solution conditions may affect absorption data, among them hydrogen-ion activity, concentration, temperature, interfering ions, irradiation, redox potential, dissolution aids, component interaction, hydrolysis, light fading, fluorescence, and plating.

Absorption data have many applications. One of the most important is the study of solution effects. The data are also widely used to follow the kinetics of chemical reactions and to determine dissociation constants and formulas of complexes. Analysts use

absorption data to identify constituents or to determine their amounts. If analysis of a solution is the purpose of the spectrophotometric measurement, all relevant variables must be under control to prevent misinterpretation of the data.

As each pure substance which absorbs selectively has a characteristic absorption spectrum, the curves are important for qualitative analysis. The contour or form of the bands and their wavelength position are the important items. Ions, molecules, and various groups such as the carbonyl group in organic compounds are involved. The infrared region is particularly useful for study of the last type, for revealing structures and purity. For mixtures, of course, a measured absorbance gives the combined absorbing power of the components. Application of such data in large quantities is made by means of machine-sorted punched cards.

In the visible region, absorption spectra are basic for applying the CIE international system (Commission Internationale de l'Éclairage) of colour specification. A recording instrument, with attached automatic tristimulus integrator, greatly facilitates calculations.

Quantitative analytical uses of absorption data depend upon the fact that the magnitude of the absorbance is a function of the concentration of the absorber. For any solution conforming to Beer's law, the expression $c = A/ab$ is used, a and b being known and A being measured for the unknown solution. If the solution does not conform to Beer's law, a simple calibration curve coordinating A and concentration may be established.

The quantitative application to systems with many components assumes that the values of A and abc for the individual components are additive for the absorption at the wavelengths employed. The concentration of n components may be obtained from absorbances at n wavelengths, where no two curves coincide or intersect, by solving n simultaneous equations. Spectrophotometers passing narrow band widths are needed for such determinations.

SPECTROSCOPY pertains to the investigation of spectra, the phenomena observed when the radiations from a particular source are separated into their constituent colours or wavelengths. Such separation results from refraction (as in a prism) or from diffraction (as in a grating). Instruments designed for this purpose are called spectroscopes if used for direct visual observation, and spectrographs if photography or other methods of recording the spectra are employed. The rainbow, formed by refraction of sunlight in rain droplets, is a beautiful and common spectrum in nature. Through spectroscopy, chemical elements present on distant stars have been identified, and an increased understanding of atomic structure and such phenomena as luminescence (*q.v.*) has been achieved. The discussion to follow deals with electromagnetic wavelengths in the range between ultraviolet and infrared, as does SPECTROSCOPY, ASTRONOMICAL. For a consideration of shorter wavelengths *see* SPECTROSCOPY, X-RAY.

I. HISTORY

The composite nature of white light was first demonstrated by Isaac Newton (1664) when he allowed sunlight entering a round hole in a shutter to pass through a glass prism and fall on a screen. This elongated and coloured image of the sun he called a spectrum. In 1800 W. Herschel studied the spectral distribution of heat from the sun with the aid of thermometers and found the maximum temperature beyond the red end, thus discovering the infrared spectrum. In 1801 J. W. Ritter, studying the effect of spectral light upon silver salts, found this action extending beyond the violet, thus discovering the ultraviolet spectrum.

The first connection between spectral colour and wavelength appeared in 1802 when Thomas Young substituted his wave theory of light for Newton's corpuscular theory, explained the colours of thin films, and calculated the approximate wavelengths of the seven colours recognized by Newton. In 1814 Joseph von Fraunhofer modified Newton's solar-spectrum experiment by substituting a narrow slit for a hole and a telescope for a screen. Under these conditions he observed the continuous spectrum of the sun irregularly interrupted by many hundreds of dark lines, still known as Fraunhofer lines. These lines were the first fiducial marks in spectra and were promptly exploited as wavelength standards for the comparison of spectral dispersion of various optical glasses. Fraunhofer constructed the first diffraction gratings by winding a fine silver wire upon two fine parallel screws or by ruling a glass plate with a diamond point, and with these he made surprisingly accurate determinations of wavelengths corresponding to the Fraunhofer lines. Although Fraunhofer and others observed that certain bright lines in the spectra of flames seemed to coincide with dark lines in the solar spectrum, it remained for G. R. Kirchhoff in 1859 to enunciate the general law connecting absorption and emission of light and to emphasize the fact that each species of atom has a uniquely characteristic spectrum.

Kirchhoff and R. W. Bunsen (1861), through systematically comparing the solar spectrum with the flame or spark spectra of the purest elements available, made the first chemical analysis of the sun's atmosphere and thus laid the foundation for spectrochemical analysis and for astrophysics (*q.v.*). In the course of these investigations, they discovered spectroscopically two new chemical elements, cesium and rubidium. These demonstrations greatly stimulated spectroscopic research and increased the need for accurate standards of wavelength. The first useful standards were provided in 1868 by A. J. Ångström, who measured the wavelengths of about 1,000 Fraunhofer lines and expressed them in units of 10^{-10} metre—a unit now known as the angstrom, abbreviated Å, and used for all spectroscopic measurements. Further refinements in standard wavelengths were made in 1887 by H. A. Rowland, who invented and applied the concave diffraction grating.

In 1881 A. A. Michelson invented the interferometer. With this instrument he measured the wavelengths of cadmium lines relative to the standard metre and attained an accuracy far exceeding that of any previous work. The wavelength of the red radiation from cadmium vapour was remeasured (1905) in terms of the standard metre by J. R. Benoît, C. Fabry, and A. Pérot, using the interferometer invented by Fabry and Pérot, and since 1907 their value—6438.4696 Å—has been internationally accepted as the primary standard of wavelength. Several thousand atomic radiations ranging in wavelength from between 2100 and 10,200 Å have been measured relative to this primary standard by interference methods, and many of these have been adopted internationally as secondary standards of wavelengths. The wavelengths corresponding to lines characteristic of any spectrum whatsoever can be obtained by interpolation between secondary standards impressed on the same spectrogram. In this manner spectroscopists have accumulated wavelength data for several million lines observed in atomic and molecular spectra, extending from the extreme ultraviolet to the far infrared and embracing nearly 30 octaves, as compared with the single visible octave that was first recognized in 1802.

These data continued to serve in the 1960s for making chemical identifications; since 1885 they have contributed mightily toward the analysis of spectral structures, interpretation of spectra in terms of quantum theory, and in the development of fruitful hypotheses concerning atomic and nuclear structure. These developments and applications of spectroscopy have unobtrusively but profoundly changed civilization (*see* LIGHT).

Any experiment in spectroscopy involves: (1) a source of light; (2) a spectroscope or spectrograph for forming the spectrum;

(3) detectors for observing or recording details of the spectrum; (4) measurements of wavelengths and intensities; and (5) the interpretation of such measurements either as chemical identifications or as clues to the structure of atoms and molecules.

II. LIGHT SOURCES

The sun and lightning flashes are examples of bright sources of light occurring in nature. Artificial light sources studied spectroscopically may be divided into two groups according as they emit continuous or discontinuous spectra. A continuous spectrum is characterized by an uninterrupted gamut of wavelengths over a considerable range. Discontinuous spectra exhibit bright lines or bands of different colours or wavelengths on a dark background. Continuous spectra are emitted by incandescent solids and liquids (gas mantle, lamp filament, hot molten metal) or by certain electrical discharges (underwater sparks). These spectra are usually dependent only on temperature and are of no use in identifying the emitting substance; their principal use in experimental spectroscopy is to provide continuous backgrounds for the production of absorption spectra of gases, vapours, solutions, or solids. Discontinuous spectra are emitted by atoms, ions, or molecules in a gaseous or vaporous state in which the individual particles are excited to radiate uniquely characteristic spectra. The particles are excited by absorbing energy either from collisions with other atoms or electrical particles or from incident radiation. Light sources producing discontinuous spectra are flames, furnaces, and electrical discharges in arcs and sparks at atmospheric pressure, or in lamps containing gases or metal vapours at reduced pressure. In the order named these sources form a rough sequence in which increasing temperatures or energies of excitation are responsible for producing different spectra.

Flames.—Since the days of Kirchhoff and Bunsen it has been customary in elementary chemistry courses to demonstrate spectrochemical identification by dipping a platinum wire into salt solutions, inserting it in a Bunsen burner, and examining the spectrum of the coloured flame with a Bunsen spectroscope or Amici prism. Because the temperature of this flame hardly exceeds 2,000° C, the kinetic energy of atomic collisions is not sufficient to produce more than the strongest lines of easily excited atoms, like alkalis and alkaline earths. These flames also emit band spectra of carbon compounds and of water vapour present in the gas and air, and other bands due to oxides formed in the flame. Higher temperatures, (about 2,500° C) are attained in an oxyacetylene flame, and atomic spectra are more fully developed. H. Lundegårdh found that when solutions of materials to be investigated were sprayed into such flames 34 elements could be determined spectrographically.

Furnaces.—An evacuated furnace, in the form of a carbon tube heated by forcing large electric currents through it, provides a source of metallic spectra in which the excitation is pure thermal energy. The temperature may be controlled between 1,500° C, where spectra begin to appear, and 3,600° C, where the carbon tube tends to fail. Small samples are placed in a porcelain boat in the tube, and the luminous vapour is imaged on the slit of a spectrograph. If a carbon plug is inserted in one end of the tube, it provides a continuous spectrum for the observation of absorption spectra of metal vapours. Such furnace spectra have been extensively investigated by A. S. King at the Mt. Wilson laboratory, in Pasadena, Calif., and the results have greatly advanced the understanding of atomic radiation processes and aided the structural analyses of atomic and molecular spectra.

Electric Arcs.—Next to the Bunsen burner the simplest source of atomic spectra is the direct-current arc consisting of an insulated holder for electrodes, an applied potential of 100 or more volts, and a resistance to limit the current to 5 or 10 amp. The actual potential drop in such metallic arcs is 20 to 40 v., most of which occurs immediately at the cathode. Atomic spectra are very fully developed in electric arcs because the temperatures range from 3,500° to 8,000° C, where all known substances melt and vaporize. Besides undergoing violent thermal agitation, many atoms collide (especially near the electrodes) with electrons or ions accelerated by the applied potential. For the study of metallic-arc spectra it is best to use solid rods of the pure metals themselves; other forms of material, *e.g.*, powders, salts, precipitates, ashes, filings, foils, refractories, minerals, are readily volatilized by placing some of the substance on the lower (positive) pole of a pure carbon arc. The direct-current arc is characterized by high intensity and effectiveness in generating the first spectra of atoms, but it is subject to erratic wandering and flickering that can impair its usefulness for accurate spectrochemical analysis unless standardized conditions are imposed. A high-voltage (2,200 v.) alternating-current arc, introduced in 1936 for quantitative analysis, reduces some of the irregularities of the direct-current arc at the expense of simplicity and sensitivity of spectral detection.

Electric Sparks.—Compared with the electric arc the high-voltage condensed spark supplies higher excitation and is easier to control. Initially the high voltage was produced by a Rhumkorff induction coil, and a Leyden jar served as a condenser. In its modern forms the spark is animated by discharges from suitable condensers connected (in parallel with the spark gap) to the secondary terminals of a transformer giving from 10,000 to 50,000 v. The condenser is charged on every half cycle to the voltage at which the gap breaks down. An oscillating current then flows in the spark circuit with an initial value of $I = V\sqrt{C/L}$, where V is the condenser voltage, C the capacity in farads, and L the circuit inductance in henrys. This initial current may be hundreds of amperes, and the result is an energetic emission of excited or ionized atoms from the electrodes. Such sparks have higher effective temperatures than arcs. Indeed, in the highest attainable vacuum these sparks produce multiple ionization until atoms are stripped of all outer electrons and the corresponding temperature is estimated at several million degrees. The ordinary spark is somewhat variable, owing to lack of constancy in breakdown potential or in the rate of decay of the oscillating discharges in each half cycle. Several devices have been introduced to control or stabilize sparks used for quantitative spectral analysis. Such devices are the synchronous auxiliary rotating spark gap and the air-blasted auxiliary gap. Any conducting solids may be used directly as spark or arc electrodes.

Other substances will serve as electrodes if they are packed in a hollow carbon rod or if they are pressed into solid form with some binder, such as pure copper powder, but in such cases the spectrum of the substance is contaminated by that of the auxiliary electrode material.

Geissler Tubes.—An important type of light source is that produced by electrical discharges in gases at reduced pressures, first demonstrated and studied by J. Plücker in 1858 (fig. 1). It usually consists of a small-bore or capillary tube of glass (or silica) connecting two bulbs or larger bore tubes containing metal electrodes that can be attached to an electrical potential difference by means of wires leading through the glass. These light sources are prepared by thoroughly exhausting the lamp, then admitting some pure gas (or vapour) through a side tube and sealing it off with a blowtorch when suitable conditions are established. The optimum pressure of gas is usually that equivalent to a few millimetres to a centimetre of mercury. When electrical potential is applied to such tubes, a sheath of ions near the cathode marks the edge of the cathode fall within which electrons released from the cathode by ion bombardment attain sufficient speed to produce new ions by collisions with gas atoms. Outside this negative glow is the Faraday dark space, and beyond it is the positive column extending nearly to the positive electrode. This positive column is responsible for most of the light emission, and being a

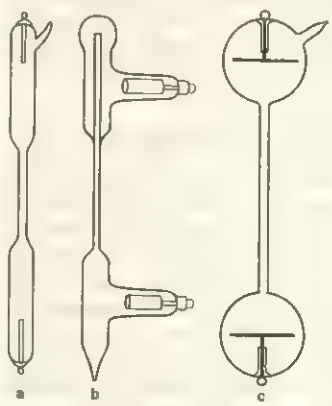

FIG. 1.—GEISSLER TUBES
(a) original, (b) modern, (c) National Bureau of Standards model

region of relatively low potential gradient and electron speeds it favours the first spectrum of the enclosed gas. A glassblower named Heinrich Geissler under Plücker's direction prepared the first practical discharge tubes and Plücker himself referred to them as Geissler tubes, a name that still clings to them. About 1920 a modified form of the Geissler tube became a spectacular type of light source for luminous coloured signs, and shortly thereafter helium, neon, and mercury lamps became commonplace. A more recent modification of the Geissler tube is the fluorescent lamp, consisting of a low-pressure mercury vapour tube whose discontinuous spectrum is partially converted to continuous bands characteristic of the fluorescent materials lining the tubes.

Hollow Cathode Discharge.—Another type of gas discharge of great utility for spectroscopic research is that devised by F. Paschen. It consists of a hollow cylindrical cathode within a cylindrical anode, and a low pressure of pure noble gas. As the pressure is reduced, the discharge retreats within the cathode until, at a pressure such that the mean free path of the electrons equals the cathode diameter, the negative glow fills the hollow cathode. The material of the cathode, or of any other metal within it, is vaporized by bombardment of the rare gas ions and excited by collisions with electrons whose maximum speeds are fixed by the ionizing potential of the sustaining gas. Since this source is operable at low pressures and low temperatures (the cathode may be cooled with liquid air), it yields atomic spectrum lines of extraordinary sharpness.

Electrodeless Discharges.—Gases or metal vapours may also be made luminous at low pressures in closed vessels without internal electrodes by placing the vessel inside a coil carrying a high-frequency current generated by either a Tesla spark generator or a vacuum-tube oscillator of ultrahigh radio frequency. The oscillating high-frequency electric fields accelerate electrons sufficiently in rarefied gases and metal vapours to excite atomic and ionic spectra. These electrodeless discharges are especially convenient for minute quantities of pure materials (such as artificial elements) or for gases and vapours that attack electrodes or that may be contaminated by them.

Linelike Sources.—When viewed through a spectroscope, any of the above-mentioned light sources will be seen as a multitude of images, one for each monochromatic radiation characteristic of the excited atoms or ions in the source. Since all practical light sources are more or less wide, these spectral images will overlap even if the spectroscope has enormous resolving power. In the case of electrical discharges in gases and metal vapours at reduced pressure, the light source is usually constructed with a long constriction to increase the intensity, and this incidentally reduces the confusion of overlapping spectral images. However, in general, it is not possible to make all light sources linelike except by imagining the light source on a narrow slit with straight parallel jaws, in which case the illuminated slit becomes the light source and the spectrum is a series of bright line images of the slit. The same effect may be obtained by substituting for the slit a cylinder of polished metal about one millimetre in diameter and using the virtual image of any light source in this cylindrical mirror as a linear light source. It is emphasized that spectral lines do not occur in nature but are consequences of using an artificial linear light source, because it gives the least confusion of overlapping images.

III. SPECTROSCOPES AND SPECTROGRAPHS

Prism Instruments.—The production of a spectrum by the use of a prism of glass or any transparent material depends upon the fact that light rays of different colours or wave-lengths are refracted differently on passing obliquely from one medium to another of different density. A composite ray of light is accordingly dispersed as well as refracted in passing through a prism, the amount of refraction being usually greater for shorter wave-lengths. The first prism spectroscopes employed by Newton and by Fraunhofer exhibited astigmatism, a type of image defect in which a point source is seen as two perpendicular image lines at different distances from the optical system. This defect was effectively eliminated in Kirchhoff and Bunsen's first spectroscope by using a collimating lens to illuminate the prism with parallel rays. Astigmatism is least and definition best in a prism spectroscope if the prism is traversed by parallel light, the slit is parallel to the prism edge, the light rays are parallel to a section perpendicular to the edge, and the rays pass through the prism symmetrically at minimum deviation. The essential parts of a simple prism spectroscope are sketched in fig. 2. Light from a source under examination enters the spectroscope through a narrow slit S located at the principal focus of the collimator lens C. Parallel rays of complex light thus fall on the prism, and rays of each component colour continue parallel in their passage through the prism and on emerging from it. The colours are refracted differently and, after passing through the telescope lens T, are focused to form a spectrum, which may be observed with an eyepiece or recorded on a photographic film.

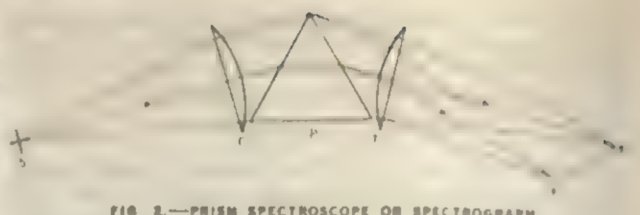

FIG. 2.—PRISM SPECTROSCOPE OR SPECTROGRAPH
S, slit; C, collimator lens; P, 60° prism; T, telescope lens; RV, red to violet spectrum

The brightness of the spectrum depends upon the way in which the slit is illuminated by the light source, upon the focal lengths and apertures of the spectrograph lenses, and upon reflection and transmission losses within the instrument. The maximum illumination is attained if the light source is large enough or so close to the slit that it subtends the same angle as the collimator lens. If the source is too small to fill the collimator with light, the brightness of the spectrum may be increased by using a condensing lens of equal aperture ratio to form an image of the source on the slit. This type of slit illumination of a stigmatic spectrograph gives a point-to-point correspondence between a section of the source, the slit, and the spectral images; it is preferred when the distribution of excitation in a source or of colour in an interference pattern is to be studied. When a perfectly uniform slit illumination is desired, as for the measurement of spectral-line intensity ratios by means of stepped filters, a condensing lens is placed just in front of the slit to form an image of the source on the collimator lens, in which case each point of the source sends light to every point of the slit and to every point of the spectral image. In either case a movable metal plate pierced with a series of openings (known as a Hartmann diaphragm) may be used to illuminate successive portions of a slit and thus record on a stationary photographic plate a number of spectra side by side for comparison and for measurement.

The light efficiency of a spectrograph, like that of a camera or telescope, depends chiefly on the ratio of the focal length F to the diameter D of the lenses. This ratio F/D may be 100/1 or more in spectrographs employed for the study of bright sources like the sun, but extremely faint sources like phosphorescence or the night sky demand unit ratio or less. A ratio of about 15/1 represents a common compromise between desired speed and the necessity of using compound corrected lenses. In such spectrographs single plano-convex or meniscus collimator and camera lenses may be used if the curvatures are chosen so as to minimize spherical aberration and coma, and the plate is tilted and bent to fit the chromatic focus. The inclined plate also usually provides an increased spectral dispersion, and the use of single lenses ensures that light losses resulting from absorption and surface reflections are a minimum.

When all relevant factors are considered, it appears that an isosceles prism with 60° angles is the best form for a spectrograph. As to prism and lens materials, there is a wide choice of optical glasses for the study of visible and near infrared spectra, but for spectral regions absorbed by glass it is necessary to use other materials, such as crystalline quartz or fluorite, in the ultraviolet, and rock salt or other alkali halides in the infrared. Dispersing Power of Prisms.—The power of any spectroscope [illegible] dispersion. It is [illegible] angle of deviation θ with respect to a [illegible] in wavelength λ [illegible] Since θ varies with the refractive index n of the prism and the refractive index varies with the wavelength λ, then the angular dispersion $\frac{d\theta}{d\lambda} = \frac{d\theta}{dn}\frac{dn}{d\lambda}$.

[illegible] depends upon two factors. The second factor $dn/d\lambda$ [illegible] of the prism [illegible] represented by an equation of the (Cauchy) form $n = a + b/\lambda^2$, where a and b are constants obtained from measured values of n for two different wavelengths. $dn/d\lambda = -2b/\lambda^3$. The negative sign merely indicates increase of n with decrease of λ. By this formula the dispersive power of a glass [illegible] varies inversely as the cube of the wavelength. For example, the dispersion at 4000 A is about eight times that at 8000 A. The other factor $d\theta/dn$ depends upon the angle of the prism and on the angle it presents to the incident light. If, as in fig. 6a, the angles of incidence and emergence be represented by i_1 and i_2 respectively, the internal angles of refraction by r_1 and r_2, the angle of the prism by α and the angle of deviation by θ, it is readily deduced from Snell's law of refraction $n = \sin i/\sin r$ that

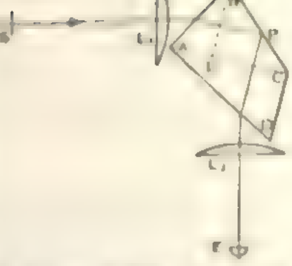

FIG. 5.—PELLIN-BROCA CONSTANT-DEVIATION SPECTROSCOPE

S, slit; L_1, collimator lens; P, Pellin-Broca prism; L_2, telescope lens; E, eyepiece

$$\frac{di_2}{dn} = \frac{\sin(r_2 + r_1)}{\cos r_2 \cos i_2}$$

or, since $d\theta = di_2$, and $r_1 + r_2 = \alpha$

$$\frac{d\theta}{dn} = \frac{\sin \alpha}{\cos r_2 \cos i_2}$$

This expression clearly shows the dependence of the dispersion upon the prism angle and the angle of incidence. A convenient equivalent expression was first deduced by Lord Rayleigh, namely

$$\frac{d\theta}{dn} = \frac{t_2 - t_1}{a}$$

where t_2 and t_1 in fig. 6b are the lengths in the prism traversed by the extreme rays, and a is the breadth of the emergent beam. When the prism is at minimum deviation and completely covered by the beam, $t_2 - t_1$ is simply the base length of the prism. The original expression for angular dispersion now becomes

$$\frac{d\theta}{d\lambda} = \frac{d\theta}{dn}\frac{dn}{d\lambda} = \frac{t_2 - t_1}{a}\frac{dn}{d\lambda}$$

When there is more than one prism, $t_2 - t_1$ is summed for all prisms, and in Amici prisms the algebraic sum is taken, the lower dispersion being regarded as negative. The angular dispersion may be expressed in radians or degrees per angstrom, but it is usually more convenient to measure linear distances x in the focal plane and express linear dispersion $dx/d\lambda$ in millimetres per angstrom. In general, if f is the focal length of the image-forming lens, $dx/d\lambda = f\, d\theta/d\lambda$.

FIG. 6.—DISPERSING POWER OF A PRISM

Resolving Power of Prisms.—It would appear from this equation that by choosing a large focal length it would be possible to separate two juxtaposed images due to light of two wavelengths, however little the wavelengths differed. Such indeed would be the case if an infinitely narrow slit were imaged as an infinitely narrow line. However, owing to the wave nature of light, any optical image is a diffraction pattern of finite size that depends both on the wavelength and on the dimensions of the optical system. An instrument is thus limited in its power to resolve images of slightly different wavelength, or closely adjacent spectrum lines. This resolving power R is expressed numerically as the ratio of a mean wavelength λ to the least difference $d\lambda$ between two wavelengths that can be recognized as a double

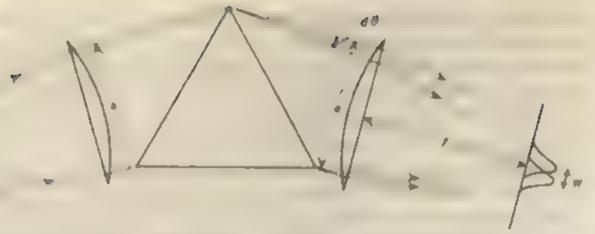

FIG. 7.—RESOLVING POWER OF A PRISM SPECTROSCOPE

image; *i.e.*, $R = \lambda/d\lambda$. Each actual image of the slit is a diffraction pattern having most of the light concentrated in a central band of finite width flanked by secondary bands of negligible intensity. If f be the focal length of the camera lens, and a the effective breadth of the beam passing through a rectangular cross section, the half width w of the central diffraction band is given by the elementary theory of diffraction as $w = f\lambda/a$. This says that the image width increases with focal length and with wavelength but decreases with aperture increase. The condition for resolution is explained in fig. 7, where the spectrum is focused on a screen by a lens of focal length f. The beams of two equal-amplitude closely adjacent wavelengths λ and $\lambda + d\lambda$ are separated by the prism an increment of angle $d\theta$. Each slit image appears as a diffraction band, and (according to Rayleigh's criterion) resolution is just effected when the central maximum of one image coincides with the first minimum of the other; *i.e.*, when the distance between centres of the two bands is w. Under these conditions the integration of the two bands gives a curve with two maxima and, if the intensity of these be rated as unity, that of the minimum between is 0.81. Experience has shown that this intensity difference is sufficient to reveal duplicity of the image, and the condition for resolution is thus $d\theta = w/f = \lambda/a$; or $\lambda = a \cdot d\theta$. By definition, $R = \lambda/d\lambda$; therefore, $R = a\,d\theta/d\lambda$, or in Rayleigh's form

$$R = (t_2 - t_1) \cdot dn/d\lambda$$

When there are several prisms, the algebraic sum is to be taken, as in the case of dispersion. An ordinary flint-glass prism of one centimetre base is found to have a resolving power for sodium-yellow light of about 1,000, but this number increases rapidly with decreasing wavelength, since $dn/d\lambda = -2b/\lambda^3$ approximately.

An infinitely narrow slit was assumed in the derivation of the theoretical resolving power, but such a slit would transmit no appreciable light. In practice it is necessary to use a slit of finite width and sacrifice some of the resolving power for the sake of intensity in the spectral images. The actual separating power with finite slits was called purity by A. Schuster, who defined a normal slit as the product of a quarter wavelength by the aperture ratio $\lambda F/4D$ and calculated that nearly 99% of the theoretical resolving power was conserved by using this normal slit. Thus, if $F/D = 20$, the normal slit for 4000 Å would have a width of 5λ or 2μ. If double the normal slit is used, the resolving power is reduced to 94% of maximum, but the intensity is doubled. Increasing the slit width to about four times normal reduces the resolving power to 80% but trebles the intensity. Still wider slits rapidly reduce the resolving power or spectral purity without appreciably intensifying the spectra of monochromatic images except where they overlap. A wide slit greatly increases the intensity of continuous background relative to that of monochromatic lines. The above definitions of dispersing power, resolving power, and spectral purity are valid also for diffraction gratings discussed below.

Grating Spectrographs.—The use of diffraction gratings instead of refraction prisms for the study of spectra brings advantages of constant and usually greater dispersion and resolution, as well as opportunity to observe extreme ultraviolet and infrared spectra for which no transparent prisms can be found. Modern gratings are made by ruling with a diamond point equidistant parallel lines on a polished plate of glass, of speculum (copper + tin) metal, or of glass on which a film of aluminum has been deposited. Those in most general use for visible and ultraviolet spectra have either 15,000, 20,000, 24,000, or 30,000 lines per inch and effective ruled areas ranging from about two to six inches. A grating with 15,000 lines per inch permits measurements in infrared spectra to 30,000 Å, but for the investigation of longer waves coarser gratings must be used. In 1910 R. W. Wood first ruled 2,000 to 3,600 lines per inch on copper plates and by proper choice of groove form succeeded in concentrating much of the visible light into relatively high orders. Such echelette gratings concentrate the greater part of infrared energy in a first-order spectrum, and they can be ruled to perform in this manner for almost any desired wavelength. Thus, a grating with 900 lines per inch may be made to function well at about 300,000 Å, 360 lines per inch about 900,000 Å, and 80 lines per inch about 1,500,000 Å. These coarse echelette gratings have ruled surfaces up to 10×20 inches in area and are usually cut in a solder surface with a steel tool. A grating ruled on a sheet of transparent glass is called a transmission grating, but it is unfeasible to rule large areas of glass without wearing down the diamond point. For this and other good reasons most gratings are ruled on opaque soft metal surfaces and are called reflection gratings. The fundamental principle is the same in both cases.

Theory of Diffraction Gratings.—The simple theory of the plane diffraction grating gives the wavelength of light as a function of the grating space and of the angles of incidence and diffraction of the light rays. Fig. 8 represents the cross section of a transmission grating in which transparent and opaque lines or spaces alternate and each pair (such as AB) is called the grating space b. If light from an illuminated slit S falls as a parallel beam on the grating at an angle of incidence i with the normal, a portion of the light passes directly through the grating aperture to produce an undeviated image, but a part of it is diffracted in the direction AD, making an angle θ with the normal. After drawing the perpendiculars CB and DB, it is seen that the difference in path traveled by corresponding rays from adjacent apertures (or the retardation as it is called) is given by the sum of the lengths CA and AD. When this retardation is equal to any integral number n of wavelengths λ, bright images of S in colour corresponding to λ are produced where the diffracted rays are brought to a focus F. This condition is simply expressed by the equation

$$CA + AD = n\lambda = b\ (\sin i + \sin \theta_n)$$

in which n represents the order number of the spectrum.

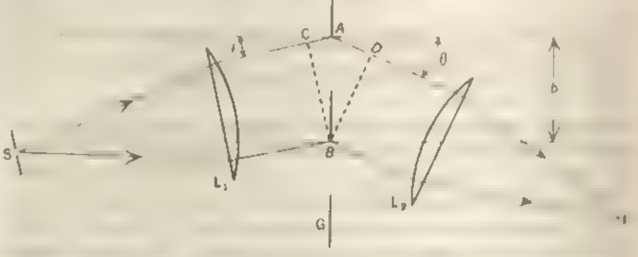

FIG. 8.—TRANSMISSION GRATING

S, slit; L_1, collimator lens; G, grating; L_2, camera lens; b, grating space; i, angle of incidence; θ, angle of diffraction; F, focused spectrum

The law of reflection gratings is similar to that of transmission gratings. Thus in fig. 9 a beam of parallel rays falls on a plane reflection grating with grating space $AB = b$. The incident light makes an angle i with the normal, and part of the light is diffracted at an angle θ. The perpendiculars AC and BD show that BC and AD are the retardations. In this case the total retardation is $AD - BC = b\ (\sin i - \sin\ \theta_n)$. Whenever this

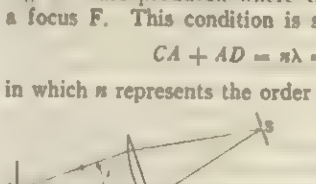

FIG. 9.—REFLECTION GRATING

S, slit; L_1, collimator lens; G, grating; L_2, camera lens; b, grating space; i, angle of incidence; θ, angle of diffraction; F, focused spectrum

equals one or more whole wavelengths $n\lambda$, a bright image is seen in colour corresponding to λ and yields the law of the grating. If the diffracted rays are on the same side of the normal as the incident rays, the two retardations are added; wherefore, the general equation for all spectra must be written $n\lambda = b\ (\sin i \pm \sin \theta_n)$, the positive or negative sign being used when the incident and diffracted rays are on the same or opposite sides of the normal, respectively. If the grating space is not too small, the groove form of the ruled lines can be controlled by shaping the diamond point in such a way that the diffracted light is largely concentrated in one general direction or spectral region. Such gratings may, for example, give an intense visible spectrum and weak ultraviolet, or vice versa. If light is incident normally on any grating, the angle i is zero and the grating formula reduces to $\pm n\lambda = b \sin \theta$, which represents a central zero-order image flanked on either side by first-, second-, third-order spectra, and so on, as $n = \pm 1$, ± 2, ± 3, and so on. It is obvious that the absolute values of wavelengths may be determined from the measurement of the grating space and of one (or two) angles. This was the method employed by Fraunhofer and by Ångström to establish standards or fiducial points in spectra.

Concave Gratings.—All plane gratings, like prisms, require the use of lenses or mirrors to collimate and to focus the incident and emergent light. To eliminate lens aberrations and limitations of light absorption, Rowland in 1881 first ruled a grating on a spherical mirror that collected light from a slit, dispersed the diffracted light into spectra, and focused them on a circle the diameter of which equaled the radius of curvature of the concave grating. All concave gratings mounted on the Rowland-circle principle exhibit strong astigmatism; *i.e.*, a point slit is imaged as a line with a length dependent on wavelength and spectral order. This astigmatism reduces the brightness of the spectra and precludes the use of diaphragms or sectors at the slit, and other observations requiring a one-to-one correspondence in the slit and its spectral images. Fortunately, this defect can be avoided either by placing horizontal lines to be focused on the circle at a greater distance from the grating than the slit or by illuminating the concave grating with parallel light, in which case the astigmatism is practically eliminated and the brightness of spectra greatly increased.

With both plane and concave gratings a great advantage is obtained by forming and observing spectra on the normal to the reflecting surface, for this gives the normal spectrum in which angular or linear distances measured either way from the grating normal are (for a considerable distance) proportional to the change in wavelength observed. Since the concave reflection grating is free from chromatic aberration and focuses all spectra on the same focal surface, Rowland took advantage of the normality of spectra and of the coincidence principle in overlapping orders of spectra to determine the relative values of the Rowland system of standard wavelengths.

Dispersion.—The explanation of dispersion by a grating is easily seen, since the formula shows that the angle θ increases or decreases with the wavelength λ. When composite light falls on the grating, it is obvious that the shorter violet waves will give an image closer to the central image than the longer red waves, and successive orders of spectra will increase in dispersion proportional to the order number.

If θ be the angle of diffraction, dispersion is defined as before by $d\theta/d\lambda$, and since (for a given position of the grating) the angle of incidence i is constant, the grating formula gives $d\theta/d\lambda = n/b \cos \theta$. This equation shows clearly how the dispersion varies directly with the order of the spectrum, and inversely as the grating space; the closer the rulings, the greater the dispersion, irrespective of the total number of grating spaces. Furthermore, the dispersion is smallest when $\cos \theta$ has its maximum value (which is unity for zero angle), *i.e.*, when the spectrum is observed normal to the plane of the grating. In this position also the dispersion is most nearly uniform throughout the spectrum, since it varies with $\cos \theta$, and in the proximity of $\theta = 0$ this trigonometric function changes very slowly. The spectrum given by a grating, unlike that given by a prism, is accordingly normal insofar as $\cos \theta$ can be considered constant. There is a certain amount of overlapping of successive orders, since $n\lambda$ may acquire the same value in different ways. For example, $\lambda = 7000$ Å in the first order will be coincident with $\lambda = 3500$ Å in the second order, and $\lambda = 4000$ Å in the third order will coincide with $\lambda = 6000$ Å in the second. When observation of a particular spectrum is desired, it is usually possible to remove the overlapping spectra by using suitable colour filters in front of the slit or selective detectors at the focus.

Resolving Power.—As in the case of the prism, the resolving power of a grating is a theoretical quantity expressing the image-separating power when the slit is indefinitely narrow; it is represented symbolically by $R = \lambda/d\lambda$ and is given in simple form by $R = nN$, where n is the order number of the spectrum and N is the total number of rulings. Thus, the resolving power of a grating depends only on the total retardation in wavelengths from the first to the last line and not on the grating space. For example, a five-inch grating with 20,000 lines per inch would have a theoretical resolving power of 200,000 in the second order, surpassing an imaginary glass prism of two metres base length. At $\lambda = 8000$ Å, $d\lambda$ would be 0.04 Å, while at $\lambda = 4000$ Å it would be 0.02 Å. This theoretical resolving power is attained only under ideal conditions, since actual resolution depends on various factors, such as the relative intensities of spectral lines, their form or structure, the width and manner of illuminating the slit, the perfection and adjustment of the optical parts, graininess or contrast of photographic emulsions, and so on.

Interferometers.—Since the resolving power of a grating is proportional to the product nN of the order number and the total number of elements, it may be increased in two ways. To increase the number of elements, the number of lines per inch may be increased or a greater number of inches ruled, but the total number of useful lines is usually limited to about 100,000 by the practical difficulties of making all grooves exactly alike and equally spaced. The alternative method of using higher orders is limited in highly dispersive gratings by the great reduction in aperture when the grating is viewed tangentially. These limitations in ruled gratings are circumvented more or less in certain interferometers known as Michelson's echelon interferometer, the Fabry-Pérot interferometer, and the Lummer-Gehrcke interferometer, all of which employ a relatively small number of elements (10 to 30) but very large spectral orders (10,000 to 100,000 or more). Since such high orders are very close together, confusion due to overlapping of many lines must be avoided by crossing these interferometers with any stigmatic spectrograph. The Michelson transmission echelon (fig. 10) consists of a number of glass plates of equal thickness t (*c.* 1 cm.) and refractive index μ, but each shorter than its predecessor. These are wrung into optical contact with each other to form a series of steps; *i.e.*, an echelon. Parallel light from a collimator, with the slit parallel to the edges of the steps, is then passed through the larger end.

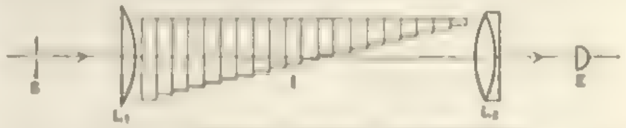

FIG. 10.—MICHELSON ECHELON INTERFEROMETER
S, slit; L_1, collimator lens; I, interferometer; L_2, achromatic lens; E, eyepiece

In each step the light is retarded an equal amount $(\mu - 1)t/\lambda$, and diffraction spectra of very high order are formed when all the transmitted beams are collected and focused by a lens. This interferometer was later improved as a reflection echelon that is not limited by the absorption of glass and has nearly four times the resolving power, since the retardation per step is $2t/\lambda$. An echelon of 30 plates each 1 cm. thick has a theoretical resolving power at 5000 Å of $30 \times 2/.00005 = 1{,}200{,}000$. This instrument has been employed for the examination of spectral line structure and for the precise measurement of relative wavelengths.

When a beam of light passes through a transparent film or plate, multiple reflections occurring at the surfaces produce interference colour effects seen, for example, in soap bubbles or in oil

films on a wet pavement. Such interference bands are relatively broad because the reflecting power is so low that only the first reflection at each surface is effective. When the reflecting surfaces are exactly parallel and the reflection coefficient is increased, the multiple reflections produce very narrow bright fringes on a broad dark background. These conditions are met in the Fabry-Pérot and in the Lummer-Gehrcke interferometers. In the former a large coefficient of reflection is obtained by depositing bright, partly transparent metal films on two glass or quartz planes. These planes are mounted face to face, separated some millimetres or centimetres, and adjusted to exact parallelism. The most common type of Fabry-Pérot interferometer (fig. 11) is the fixed-etalon type, in which the plates are maintained at a fixed distance by being pressed against a separating ring spacer or etalon. When it is used with monochromatic light and viewed axially, circular interference bands known as Haidinger's fringes are seen at infinity. When it is used with complex light the overlapping of fringes belonging to neighbouring spectral lines is avoided by crossing the interferometer with a stigmatic spectrograph. The order of interference at the centre of the pattern for wavelength λ is in general a whole number n plus a fraction ϵ, determinable from the diameters of successive rings. The double distance between the interferometer plates is $2D = \lambda\ (n + \epsilon)$ for wavelength λ, or $2D = \lambda'(n' + \epsilon')$ for another wavelength λ'. Thus the simple proportion $\lambda/\lambda' = (n' + \epsilon')/(n + \epsilon)$ offers an opportunity for the precise comparison of wavelengths, and this is in fact the method employed for the establishment of secondary standards of wavelength measured relative to the primary standard (red radiation from cadmium), which was itself found to be 6438.4696 Å by comparison with the meter. (*See* INTERFEROMETER.) This method of comparing wavelengths has been used extensively also for measuring the ratios of wavelengths in vacuo and in gases and thus determining the refractive indexes and dispersions of gases, notably air. In addition, the Fabry-Pérot etalon interferometer has proved the most effective instrument for the measurement of exceedingly small wavelength differences, which appear, for example, in hyperfine structure, isotope shifts, pressure shifts, and so on. Besides simplicity, stability, and freedom from defects, this interferometer possesses a large advantage in the flexibility of its resolving power, since this is equal to the product of the spectral order n by the effective number of reflections N. With a reflection coefficient of 0.75 the value of N is about 10, and with 0.90 the effective number of reflections is about 30. Thus, a Fabry-Pérot interferometer with silver mirrors reflecting 0.90 is equivalent to a reflection echelon of 30 plates having plate thickness equal to the etalon separator. The echelon plates have a fixed thickness, whereas the Fabry-Pérot plates may be separated as desired to increase resolving power.

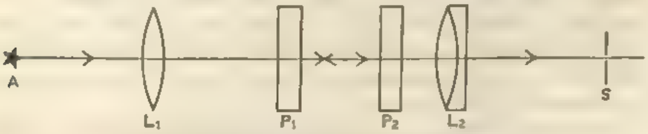

FIG. 11.—FABRY-PÉROT INTERFEROMETER

A, light source; L_1, collimator lens; P_1 and P_2, interferometer plates; L_2, achromatic projection lens; S, spectrograph slit

In fact, the highest resolving powers on record have been attained with Fabry-Pérot interferometers, and the most detailed and reliable results on hyperfine structure must be credited to them.

The Lummer-Gehrcke interferometer consists of a long unsilvered plate with perfectly plane-parallel surfaces in which a high reflection coefficient is obtained by directing the entering light beams so that they are reflected at nearly the critical angle (fig. 12). The greater part of the light is reflected at each internal reflection, but the remaining fractions emerge with equal retardations as parallel refracted beams that may be collected and focused by a lens to form identical sets of interference patterns above and below the optic axis. The resolving power is again nN, where n is the order of interference (retardation) and N the effective number of reflections or emergent beams, which usually ranges from 10 to 20. The practical resolving power of the Lummer-Gehrcke interferometer has been found to be about equal to the length of the plate measured in wavelengths. This instrument has been employed successfully for the observation of hyperfine structure, isotope shifts, and for studying Zeeman patterns.

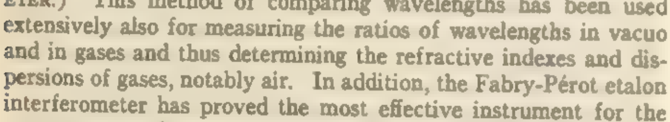

FIG. 12.—LUMMER-GEHRCKE INTERFEROMETER

A, light source; L_1, collimator lens; I, interferometer; L_2, achromatic projection lens; S, spectrograph slit

The most famous of all interferometers is that invented by Michelson in 1881 and fully exploited by him in his classical investigations of "ether drift," sharpness of spectral lines, and evaluation of the international metre in wavelengths of cadmium radiations.

IV. METHODS OF OBSERVATION

There are in general four ways of observing spectra: visually, photoelectrically, radiometrically, and photographically; each has advantages and limitations.

Visual.—Although the average human eye is extraordinarily sensitive for green light (5500 Å), its sensitivity declines rapidly to zero for infrared ($\lambda > 7700$ Å) and ultraviolet ($\lambda < 3800$ Å). Being highly selective, variable, localized, and restricted to one octave, visual methods of observation are relatively unimportant in spectroscopy.

Photoelectric.—As a substitute for the human eye, the electric eye or photoelectric tube may be employed for the investigation of spectra in limited ranges. Briefly, the photoelectric tube consists of two metal electrodes in an evacuated glass tube. The anode is maintained at a positive potential with respect to the cathode. When radiation falls on the cathode, the liberated electrons are drawn across the evacuated space to the anode. This flow of electrons constitutes a photoelectric current that is directly proportional to the incident energy. Since these photoelectric currents are usually very small, they are magnified by the use of thermionic amplifiers, or, in the case of feeble radiation, use is made of a Geiger-Müller tube, in which each electron emitted gives rise to a pulse of current. Since 1940, multiplier phototubes, in which enormous amplification is obtained by a sort of chain reaction, have become popular as detectors and intensity recorders of spectral lines. All photoelectron emitters, *e.g.*, Na, Zn, Cd, Mg, are highly selective and usually most efficient in the ultraviolet. By depositing thin films of heavy metals or compounds, *e.g.*, CsO, PbS, photoelectric sensitivity may be extended to near infrared but not much beyond 40,000 Å.

Radiometric.—A unique and important class of radiation detectors, responding to the heating effect of the radiation, is found in blackened radiometers, radiomicrometers, thermopiles, and bolometers. They are unique because they are nonselective, and important because their sensitivity extends from ultraviolet, through visible, to far infrared spectra. The radiometer is a blackened vane supported some distance from the axis of rotation of a glass or quartz fibre *in vacuo*. When radiation is absorbed by the vane, the supporting fibre is twisted through an angle proportional to the incident radiation. The radiomicrometer is essentially a moving coil galvanometer of the D'Arsonval type. A single thermocouple is suspended by a quartz fibre with the plane of the couple coil in the line joining the poles of a magnet. When radiation falls on the thermocouple junction, the electric current generated acts to turn the couple in the magnetic field. The thermopile consists of one or more junctions of dissimilar metals; *e.g.*, bismuth and antimony or silver, iron, and constantan (alloy of nickel and copper). If radiation falls on alternate junctions, a galvanometer in the circuit will give a deflection proportional to the heating effects. All radiation-detecting and measuring devices that depend on the initial conversion of radiant energy into heat energy and finally into mechanical or electrical energy

are extremely inefficient, as are all heat engines. The feeble final effects of radiation may be magnified up to about 200 times by suitable amplifiers, but thermopile currents that produce galvanometer deflections of the same magnitude as Brownian-motion effects obviously cannot be amplified to advantage.

The bolometer, devised by S. P. Langley in 1880, consists of two similar very thin strips of metal, usually platinum, which form two arms of a Wheatstone bridge. The strips are blackened on one side, one strip is shielded, and the other is exposed to radiation. The absorption of radiation by one strip increases its temperature, changing its electrical resistivity and producing a deflection of the galvanometer. With his bolometer Langley in 1888 mapped the solar spectrum to 55000 Å by using a spectrometer with rock-salt lenses and prisms and passing the spectrum over the bolometer strip by rotating the prism. The galvanometer readings were recorded on photographic paper whose motion was coordinated with that of the prism. The same basic principles were used in the 1960s with improved instrumentation in all automatic recording of spectra scanned either by photoelectric or radiometric detectors.

Photographic.—The actinic action of radiation on silver salts is fairly effective throughout many octaves of spectra, from blue to extreme ultraviolet, but the maximum sensitivity is usually in the blue. Photographic image formation rests on a latent and lasting effect produced by light in microscopic silver-halide crystals suspended in gelatin coated thinly on a glass, film, or paper base. The crystals affected by light are readily reduced to metallic silver by a suitable reducing agent or developer, and the unreduced silver halide is dissolved out with a fixer, usually hypo, thus producing images composed of tiny silver grains, the density of which is a function of the intensity or total energy incident upon the emulsion. Although gelatin is highly transparent to waves longer than 3000 Å, it is strongly absorbent for shorter waves and practically opaque below 2000 Å. In order to record spectra below 2000 Å, in 1901 V. Schumann effectively eliminated the shielding effect of gelatin by depositing silver salts on glass plates with only enough gelatin to support them. Another way to circumvent the ultraviolet absorption of gelatin was discovered in 1921; it consists of coating an ordinary photographic plate or film with a thin film of oil or suitable organic substance that fluoresces in ultraviolet light and emits longer wave radiation not absorbed by the gelatin (*see* PHOTOGRAPHY).

In 1873 H. M. Vogel discovered that the light sensitivity of silver salts could be extended to longer waves by bathing ordinary plates in certain dye solutions. By 1900 the incorporation of suitable photosensitizing dyes in emulsions produced panchromatic plates that were sensitive to the entire visible spectrum, and after 1930 the synthesis and application of an important series of polycarbocyanine dyes extended the sensitivity of photographic emulsions into the infrared to about 13000 Å. Since large intervals of spectra and multitudes of spectral details could thus be recorded simultaneously, it follows that more spectrographic observations have been made photographically than by all other methods. In addition to being applicable in an enormous range of wavelengths, the photographic method provides a permanent, detailed record of a spectrum that can be conveniently examined or accurately measured by any number of persons as often as desired without repeating the experiment. Furthermore, photographic exposures are cumulative, and the photographic method thereby derives additional advantages in integrating the light from flickering or intermittent sources and in recording extremely faint images by giving long exposures. Although the absolute sensitivity of a photographic emulsion may vary considerably with wavelength, it can often be regarded as constant over a limited range of spectrum and in any case can be calibrated as a function both of wavelength and intensity, thus providing a convenient method of measuring the relative intensities of spectral lines. This photographic-photometry method was developed about 1925 for the purpose of testing quantum rules for the relative intensities of certain lines, and since 1930 it has become standard practice in quantitative spectrochemical analysis.

It should be emphasized that any selective receiver (eye, phototube, or photographic plate) employed for measuring the relative intensities of spectral lines requires calibration by comparison with nonselective receivers; *e.g.*, thermopiles.

WELCH SCIENTIFIC CO

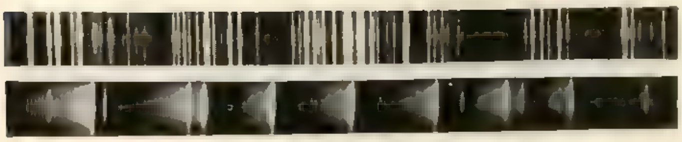
Reproductions of the bright-line spectra of selected elements found on the sun, and of the solar spectrum with principal Fraunhofer lines A, B, C, D, E, F, G, H, K. A and B are caused by terrestrial oxygen (O_2); C and F belong to hydrogen; D represents sodium; E, G, H, K indicate calcium mainly. Also shown are spectra for mercury and barium

V. MEASUREMENTS

Spectroscopic measurements are concerned essentially with energy distribution as a function of wavelength. This function is characteristic primarily of the light source and secondarily of its operating conditions, assuming that the spectrograph is nonselective. If the energy changes slowly from point to point in large intervals of spectra, the spectra are called continuous. They may be either emission spectra or absorption spectra and consist usually of one broad band.

If the spectral intensity changes rapidly from point to point and undergoes sudden inflections, the spectra are called discontinuous. Such spectra also may be either emission spectra or absorption spectra; they usually consist of hundreds or thousands of lines. The division of observable spectra as continuous and discontinuous, either in emission or in absorption, is a broad but useful classification. Each class contains an enormous number of examples, some of which may be grouped according to certain criteria into smaller classes. The following examples will illustrate the principal classes of spectra that are subjected to observation and measurement.

Emission Spectra.—All self-luminous sources yield emission



LINE AND BAND SPECTRA OF NITROGEN

spectra, which are of different types according to the nature of the light source. Spectrally dispersed light from glowing gas mantles, electrically heated metallic filaments, or hot molten metals are continuous over great ranges of wavelengths, and for blackbody radiation the wavelength of maximum intensity is an inverse function of absolute temperature. It follows that such substances cannot be distinguished by means of their spectra as long as they remain in the solid or liquid state.

The effects are quite different when the substances examined are in a state of luminous gas or vapour. They then emit characteristic discontinuous spectra by which they can be uniquely identified, whether they are excited in the laboratory or in a celestial body far away. These spectra consist of bright lines or bands variously spaced on a dark background.

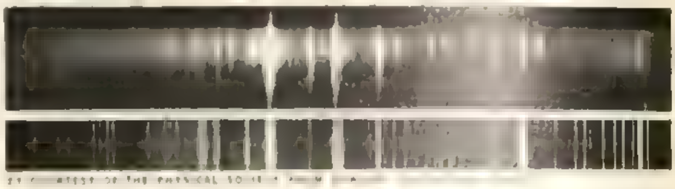
Line spectra are characteristic of atoms or ions, while band spectra originate in molecules. The former consist of a certain distribution of slit images of different intensity and usually of various types, such as partially self-reversed lines, sharp lines, diffuse lines, unsymmetrical lines, and complex lines with two or more components. Partially reversed or easily absorbed lines always indicate that the normal state or some low energy state of the atom or ion is involved. The relative sharpness or diffuseness of lines is determined by such factors as pressure, temperature, mass, and excitation. Complexity of spectral lines is referred either to different isotopes of the same element (isotope shift) or to interaction of valence electrons with a spinning isotopic nucleus (hyperfine structure).

In a band spectrum a great number of fine lines are closely and regularly placed in each band, becoming more and more crowded near the band head. The band heads are on the short-wave side of the line groups in some band systems, and on the

"RED" SPECTRUM OF HYDROGEN SHOWS ITS CHARACTERISTIC BALMER SERIES OF LINES IN THE VISIBLE AND NEAR ULTRA-VIOLET REGIONS

long-wave side in others. In pure gases the commonly observed band spectra characterize molecules consisting of two similar atoms, such as H_2, He_2, N_2, O_2. The line spectra of metals excited in flames, arcs, or sparks operated in the free atmosphere are usually accompanied by band spectra characteristic of monoxides (such as CaO, BaO, ScO, LaO) formed by the oxidation of the metals. Arc spectra frequently show band spectra identified with NO and CN, as well as line spectra of N, O, Ar, and C, the principal constituents of the atmosphere. Many dipole molecules unknown to ordinary chemistry but recognized spectroscopically are apparently formed only under special conditions existing in the light sources.

No two substances yield the same spectrum, and, consequently, the chemical nature of substances can be determined spectroscopically. Thus, glowing atomic hydrogen is characterized by a bright line in the red, besides progressively weaker ones of shorter wavelength, and, since these are exhibited by nothing but hydrogen, they serve to disclose the presence of atomic hydrogen wherever it occurs in the luminous state. Each of the known chemical elements has its distinctive family of spectral lines, differing in distribution, relative intensity, and total number but always the same under the same conditions of excitation. The same element, however, under radically different excitation conditions will emit entirely different spectra. The most easily excited spectrum is that of neutral atoms in possession of all their valence electrons, but, if the excitation is violent enough to remove one electron from each atom, the resulting ions when excited radiate another characteristic spectrum. A third type of spectrum is emitted when the atoms are doubly ionized by removal of two electrons, and so on until only one outer electron remains. Thus, each element or atom has as many characteristic spectra as it has electrons. In most arc or spark sources generating atomic spectra of a pure element, two or more spectra appear simultaneously, with one usually predominating. When two or more elements with comparable excitation characteristics are abundant in a light source, each element emits its own spectra essentially the same as if all other elements were absent. The spectra of complex substances, such as ores, minerals, metal alloys, and chemical mixtures, thus reveal simultaneously all the types of atoms and ions that are excited in the light source. Such supernumerary line spectra often have superposed on them band spectra of molecules formed and excited in the same light



SPECTRA OF STRONTIUM: (ABOVE) SPARK, (BEL[illegible] FLAME LINES ARE REDUCED IN INTENSITY IN THE SPARK SPECTRUM, W[illegible] ENHANCED" OR "SPARK" LINES ARE INTENSIFIED

source, as well as lines and bands of atmospheric elements. Also seen is a more or less intense continuou[illegible]nd, which may be traced either to unquantized radiation [illegible]toms, to a continuous spectrum from incandescent oxid[illegible]ight source, or to stray reflected or scattered light in the spectrograph; sometimes to all three

In such complicated cases it is clear that only experienced spectroscopists can interpret the spectrogra[illegible]ly. Familiarity with the spectra of various elements ofte[illegible]n experienced observer to identify lines or bands at [illegible]he distribution and relative intensities in certain group[illegible]ized and recognized in the same way that constellations a[illegible]gnized among stars. In theory any unknown spectrun[illegible]ture of spectra can be identified by comparing it with al[illegible]ectra of known elements excited under similar condition[illegible]ractice the endless labour of repeatedly observing th[illegible]rison spectra is avoided by measuring wavelengths corres[illegible]o the unknown lines and comparing these with wavelength t[illegible]bles of identified lines compiled for this purpose

For purposes of chemical identification [illegible] wavelengths and the relative intensities of lines in spectra may be regarded as constants of nature, but closer examination shows that in any given spectrum certain variations are produced by different excitation conditions. Thus, spectral wavelengths are generally slightly increased as the total pressure of gas or vapour surrounding the radiating particles is increased. Such pressure shifts are further correlated with atomic diameters and with atomic energy levels.

Also the wavelengths are either decreased or increased, according to Doppler's principle (*see* DOPPLER EFFECT), when the radiating source approaches or recedes from the observer. In astrophysics this principle has disclosed the sun's rotation, the radial velocities of stars, and an apparently expanding universe; whereas in the laboratory it explains (when combined with the kinetic theory of gases) the intrinsic natural width of spectral lines as a function of $\sqrt{T/M}$, in which T represents absolute temperature and M molecular weight. When standard wavelengths in the solar spectrum are measured, it is necessary to correct the observations for Doppler effect due to the relative motion of the sun and the spectrograph.

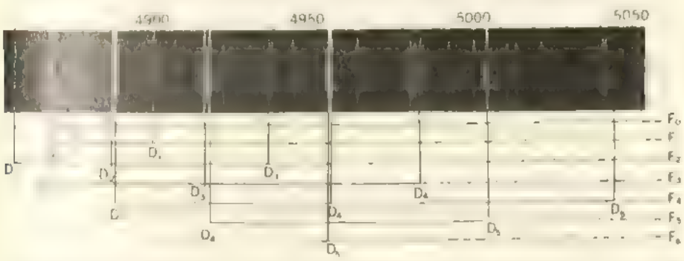
Again, with few exceptions, all atomic spectral lines are split into three or more components when the radiating particles are in strong magnetic fields (*see* ZEEMAN EFFECT), and, similarly, many lines either shift or widen or divide into resolved compo-

nents when the radiating particles are subjected to strong electric fields (*see* STARK EFFECT).

From the general theory of relativity (*q.v.*) A. Einstein in 1917 concluded that wavelengths characteristic of atoms should increase in strong gravitational fields. This effect is quite inappreciable in the laboratory, but it appears to be present in the solar spectrum, and especially in the spectra of very dense stars.

The most striking changes in relative intensities of lines belonging to a particular spectrum occur when excitation conditions favour the partial self-reversal of selected lines. These variations of spectral characteristics are highly objectionable in standard wavelengths and in spectrochemical analysis, but they are of primary importance in spectroscopic research, since they yield information about atomic structure and the mechanism of radiation. Consequently, when truly invariable spectra are desired, they may be produced by carefully specifying and reproducing the light source in such a manner that spectral variations are eliminated or minimized; but if atomic structure is being investigated, it is desirable to effect the largest practicable changes in spectra and relate these to variations in the light sources. In any case, it is evident that some means of accurately expressing the positions of lines in a spectrum is of primary importance.

Wavelengths.—Measurements of spectra become directly comparable with each other only when they have been converted to the scale of wavelengths (or frequencies) of the radiations that produce the spectral lines. The credit for introducing this scale into spectroscopy is due to Ångström, who described the spectrum of the sun in terms of wavelengths in 1868, and since



HIGH-DISPERSION ARC SPECTRUM OF IRON SHOWS MULTIPLET OF 15 LINES AND PLAN OF ITS STRUCTURE

that time the positions of practically all known spectral lines have been expressed in wavelengths. The unit of wavelength in spectroscopy is a ten-millionth part of a millimetre, or 10^{-10} m. It is called the angstrom and is symbolized by Å. In these units, the visible spectrum ranges from about 3800 Å (violet limit) to about 7700 Å (red limit). Extremely short waves, in particular those observed in Röntgen- or X-ray spectra, which range from about 0.1 Å to about 100 Å, are more conveniently expressed in still smaller units, and for this purpose the X unit, approximately 1/1000 Å, is generally used. Similarly, very long optical waves, in particular the far infrared heat waves, are more conveniently expressed in larger units, and for this purpose the micron μ = 10,000 Å is commonly used. Summarizing: 10^{-6} m. = 0.001 mm. = 1 μ = 10,000 Å = 10,000,000 X. Wavelengths ranging from 6 Å to 5,000,000 Å have been measured in spectra associated with valence electrons, but these limits will surely be extended in both directions.

Absolute wavelengths cannot be determined directly from prisms but have been measured with gratings and interferometers by methods outlined in the discussion of these instruments. Because such measurements are relatively difficult and tedious, they have been made only for the purpose of setting up standards of wavelength, and in all other spectroscopic work, whether with prisms or gratings, wavelengths are deduced by interpolation between adopted standards.

Wave Numbers.—In the interpretation of spectra as transitions between quantized energy states ($E_2 - E_1 = h\nu$), it is necessary to express the positions of the spectral lines on a frequency (ν) scale instead of a wavelength scale. Unfortunately, neither nature nor human ingenuity has disclosed a method of directly measuring the oscillation frequencies corresponding to light waves. These frequencies, defined as the number of waves that pass a given point in one second, must be derived from the relation $\nu = c/\lambda$, in which c is the velocity of light and λ is the observed wavelength. In order to make these frequencies independent of the medium through which the light passes, both c and λ must be evaluated *in vacuo*. Since the velocity of light is very great (about 29,979,300,000 cm. per second) and a light wave is very small (0.00000550 cm. for brightest visible light), the frequency is an extremely large and awkward number (545,000,000,000,000 in this example). In spectroscopy it has become common practice to replace the ungainly actual frequencies by wave numbers, representing the number of waves in one centimetre of vacuum and symbolized by cm.$^{-1}$. If the wavelength has been measured in air, it must be multiplied by the refractive index of air to change it to its value *in vacuo*. The National Bureau of Standards prepared a table of wave numbers for the convenient conversion of wavelengths in standard air to wave numbers *in vacuo*. For example, 5500.000 Å = 18,176.769 cm.$^{-1}$. Such wave numbers of observed spectral lines are strictly proportional to the natural frequencies and to the corresponding changes in atomic or molecular energy.

Standard Wavelengths.—In modern spectroscopy the primary standard of wavelengths is that of the red radiation from cadmium vapour first measured relative to the international metre bar by interferometer methods in a classical experiment by Michelson in 1892 (*see* PHYSICAL UNITS). Benoît, Fabry, and Pérot in 1905 found that 1 metre contained 1,553,164.13 of these waves, and the reciprocal of this number has been internationally adopted as the definition of the primary standard of wavelength: "the wavelength of the red ray of light from cadmium is 6,438.4696 angstroms in dry air at 15° C. on the hydrogen thermometer, at a pressure of 760 mm. of mercury, the value of g being 980.67 (45°)." The probable error of this absolute value is of the order of 1 part in 16,000,000; *i.e.*, somewhat less than the least error in the intercomparison of two metre bars.

The Eleventh General Conference of Weights and Measures, on Oct. 14, 1960, unanimously adopted a resolution defining the metre as the length equal to 1,650,763.73 wavelengths *in vacuo* of the radiation corresponding to the transitions between the $2p_{10}$ and $5d_5$ levels of the krypton-86 atom. The reciprocal of this number gives the wavelength 6057.80211 Å, and the angstrom is simply 10^{-10} m. That wavelength thus became the international standard of length, as well as the primary standard of wavelength.

A method of measuring, with high accuracy, the ratio of two different wavelengths was outlined in principle in the brief discussion of the Fabry-Pérot etalon interferometer. After 1907 this method was used in several laboratories to determine, relative to the primary standard, the wavelengths of selected lines that might serve as secondary standards. The wavelengths of several thousand atomic radiations characteristic of helium, neon, argon, krypton, xenon, iron, and titanium in laboratory spectra, and well over 1,000 lines in the sun's spectrum, have thus been measured, but only such mean values are accepted as secondary standards by the International Astronomical Union as have been independently and concordantly measured in at least three laboratories. For example, in the iron spectrum interferometric measurements have been made on thousands of lines with wavelengths ranging from 2101 Å to 10,216 Å, but only 306 secondary standards ranging from 2447 Å to 6677 Å have been adopted. These iron secondary standards are believed to be accurate within ±0.001 Å, but to insure their reproducibility the source is carefully specified as "the Pfund arc operated between 110 and 250 volts, with 5 amperes or less, at a length of 12–15 millimetres used over a central zone at right angles to the axis of the arc, not to exceed 1–1.5 millimetres in width, and with an iron rod 6–7 millimetres diameter as the upper pole and a bead of iron oxide as the lower pole."

It seemed certain in the 1960s that the iron standards would be superseded by superior thorium wavelengths emitted by electrodeless lamps excited by ultrahigh-frequency electromagnetic oscillations. In the absence of official standards in the extreme ultraviolet, spectroscopists have been forced to use preliminary

values obtained by the coincidence method of overlapping orders in grating spectra or by direct calculation from spectral series formulas or from spectral terms accurately determined from longer waves.

Interpolation of Wavelengths.—The wavelengths corresponding to lines in any spectrum whatsoever are readily determined by interpolation between standards, provided that the spectrum of the international iron arc is recorded with the same spectrograph. For this purpose the spectrum of the source under examination is photographed through one portion of the slit, and the arc spectrum of iron through one or both of the adjacent portions, so that two spectra in juxtaposition, or slightly overlapping,

SPECTRUM OF OXYGEN (MIDDLE) PLACED OVER THAT OF IRON TO COMPARE AND MEASURE WAVELENGTHS

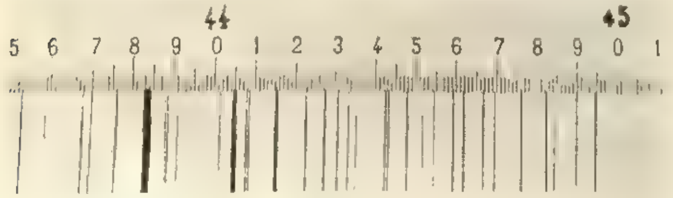
are obtained. For accurate determinations the relative positions of spectral lines and standards are measured with a micrometer or comparator consisting of an accurate screw designed to translate the spectrogram under a microscope so that the lines and standards are brought successively into coincidence with a reticle. The positions of the lines are then read from a scale that indicates complete turns of the screw, and a divided drumhead that registers fractions of a turn.

In prismatic spectra the dispersion increases rapidly as the wavelength diminishes, and linear interpolation will not give correct results. Approximate values of wavelengths may be obtained by interpolation on a graph of dispersion versus wavelength constructed by plotting scale readings of standard lines as abscissas and wavelengths as ordinates. The most accurate method of determining wavelengths in prismatic spectra is by mathematical interpolation with the Hartmann dispersion formula, which gives a simple relation between wavelength λ and linear scale reading r,

$$\lambda = \lambda_0 + \frac{c}{r - r_0}$$

where λ_0, c, and r_0 are constants that can be evaluated from the solution of three simultaneous equations containing three known wavelengths or standard lines and their corresponding scale readings.

Relative wavelengths are most readily obtained from diffraction spectra, since linear interpolation between standards is justified by the fact that the dispersion is constant (or nearly so) in a given grating order or setting. If r_i and r_f are millimetre scale readings for initial and final standards λ_i and λ_f on a spectrogram, the dispersion $d = (\lambda_f - \lambda_i)/(r_f - r_i)$ Å per mm. The product of this dispersion constant and r_i subtracted from λ_i gives a constant λ_o, which, on any calculating machine, can be automatically added to any dr_x, and the final result is $\lambda_x = \lambda_o + dr_x$. Both in prismatic and in grating spectrograms intermediate standards should be measured; in the former case to test the fit of the dispersion formula and in the latter to test the normality of the spectrum. If the calculated values deviate from the true standards, a plot of such deviations will reveal the proper corrections to apply to the wavelengths calculated for the other measured lines. Under the most favourable conditions such interpolated wavelengths are probably correct within a few thousandths angstrom. All wavelength measurements relative to iron standards are obviously facilitated by reference to a good photographic map of the iron-arc spectrum permitting instant identification of the standards.



PARTIAL PHOTOGRAPHIC MAP OF IRON-ARC SPECTRUM YIELDS APPROXIMATE WAVELENGTHS

Intensity Measurements.—The exact determination of relative intensities of the various parts or lines of a spectrum is in most cases as important as exact wavelength measurement, but this phase of spectroscopy had a tardy development, partly because of experimental difficulties and partly because the important applications were mostly unrecognized before 1925. Only heat-absorbing detectors show a linear and nonselective response to spectral intensity, and since they are typically inefficient heat engines, their use has been restricted mainly to infrared spectra. All other detectors, being nonlinear and selective, require calibration, but this is a complicated and difficult operation, especially in the extreme ultraviolet, where heat detectors are relatively insensitive. Consequently, even the most modern tables of identified spectral lines contain only rough estimates of line intensities on arbitrary scales, which differ from spectrum to spectrum and frequently from region to region in the same spectrum. These arbitrary intensity scales usually represent visual estimates of photographic blackening, and they range from 1 to 10 or 1 to 1,000 or 1 to 10,000. Such estimates have no definite meaning and no truly quantitative value.

After 1925 the need for accurate measurements of spectral-line intensities was stressed by the new quantum theory of atomic spectra and by a rebirth of quantitative spectrochemical analysis. Mathematicians predicted important relationships between line intensities and multiplet structures or quantum numbers, and experimental spectroscopists promptly devised methods of testing the theory. Simultaneously in applied spectroscopy quick methods of accurate chemical analysis based on the measurement of spectral-line intensity ratios were empirically developed. Since almost all spectroscopic observing was done photographically, the quantitative determination of intensities from spectrograms required the construction and use of suitable microphotometers or microdensitometers to measure the photographic densities of spectral-line images. By making a series of exposures of known ratio, either in intensity or in time, photographic density as a function of radiation intensity of a given wavelength can be determined for the particular type of photographic emulsion employed, and from density measurements at different wavelengths in a comparison spectrum of known energy distribution true intensity ratios can be deduced. Standard sources of known energy distribution are found in the blackbody or in metal-filament lamps operated at specified colour temperatures. Photographic sensitivity and contrast may be regarded as constant in narrow spectral regions, such as those encompassed by compact multiplets, hyperfine multiplets, Zeeman patterns, or close line pairs, and in these cases relative intensities of component lines are determinable without spectral energy calibration.

Absorption Spectra.—In 1859 Kirchhoff gave mathematical and experimental validity to the following law: "The ratio between the powers of emission and the powers of absorption for rays of the same wavelength is constant for all bodies at the same temperature." From this it follows that a transparent body cannot emit light, and one that radiates a continuous spectrum must be opaque. Further, a gas that radiates a line spectrum will absorb the lines that it radiates at the same temperature. For example, lines observed in laboratory arcs as emission spectra of 66 elements or compounds have been identified as absorption lines in the spectrum of the sun. As a consequence of Kirchhoff's law, practically everything that has been said about emission spectra applies also to absorption spectra. There are, however, some experimental conditions that permit molecular identification and quantitative chemical analysis by means of absorption spectra that cannot be duplicated in emission spectra.

Thus in the analysis of inorganic compounds (salts, minerals, etc.) by emission spectra, the light sources (flames, arcs, sparks) commonly used for exciting the spectra completely dissociate the compounds, revealing intense spectra of the metallic atoms and of unstable compounds formed in the light source, whereas the

spectra of the halogens or radicals are either unobserved or masked. Thus, essentially the same atomic emission spectrum is observed with various metallic compounds (halides, oxides, carbonates, sulfates, etc.). Similarly, organic molecules (tissues, dyes, etc.) are atomized by the heat and excitation of emission sources, revealing only spectra of metallic impurities that may be present, while the emission spectra of carbon, hydrogen, and oxygen are indistinguishable from those emitted by atmospheric constituents, dissociated carbon dioxide, and water vapour.

Often, however, inorganic compounds in solution and organic compounds in general exhibit characteristic absorption spectra that distinguish them from each other. Since absorption spectra of compounds are observed at relatively low temperatures, the molecules are stable and unimpaired, but since the substances are then usually in a liquid or solid state, rather than in a gaseous state, the absorption will depend on the energy content of the molecules and on the perturbing effects of surrounding molecules. These absorption spectra, therefore, usually consist of one or more broad bands in which the energy distribution is characteristic of the compound. If an unknown mixture contains two or more absorbing compounds, their identity and relative amounts can be determined if the absorption bands are sufficiently different in wavelength and accurately defined to permit an estimation of their relative intensities. Extraordinarily narrow absorption bands, almost linelike, are exhibited by solids, solutions, and glasses containing atoms that possess one or more *f*-type electrons (rare earths with atomic numbers 58 to 71 and 90 to 103).

ABSORPTION SPECTRA: NEODYMIUM GLASS (TOP); POTASSIUM VAPOUR (BOTTOM)

Narrow lines belonging to molecular spectra of oxygen (O_2) and water vapour (H_2O) are readily observed in absorption but not in emission. Red and infrared bands of these molecules invariably appear on spectrograms made in the laboratory with long-focus spectrographs provided that the light source emits a continuous background, and they are outstanding features of the solar spectrum, especially when the sun is near the horizon and shines through the thickest layer of terrestrial gas and vapour. Similarly, because of the great depth of absorbing vapours in the solar atmosphere, the atomic spectrum of iron is much more fully revealed in the Fraunhofer spectrum than has been observed in laboratory emission spectra. *See* also SPECTROPHOTOMETRY.

VI. APPLICATIONS

The principal applications of spectroscopy are to: (1) chemical and physical analysis; (2) research on atomic structure and the mechanism of radiation; and (3) investigations of some properties of atomic nuclei.

Spectrochemical Analysis.—That a system of qualitative chemical analysis could be based on spectroscopic observations was first convincingly demonstrated by Kirchhoff and Bunsen, who (1860) applied spectroscopy to the discovery of two alkali metals (Rb and Cs) and to the identification of chemical elements in the sun. Save for chemical analysis of meteorites that fall to earth, there was no way to learn anything concerning the chemical and physical conditions of celestial bodies except from an analysis and interpretation of the light those remote bodies emit. Consequently, the challenge and urge to apply spectroscopy to astronomy was irresistible, and an amazing accumulation of information on the radial motions, chemical compositions, and physical conditions of planets, comets, stars, and nebulae constituted the science of astrophysics in the 1960s.

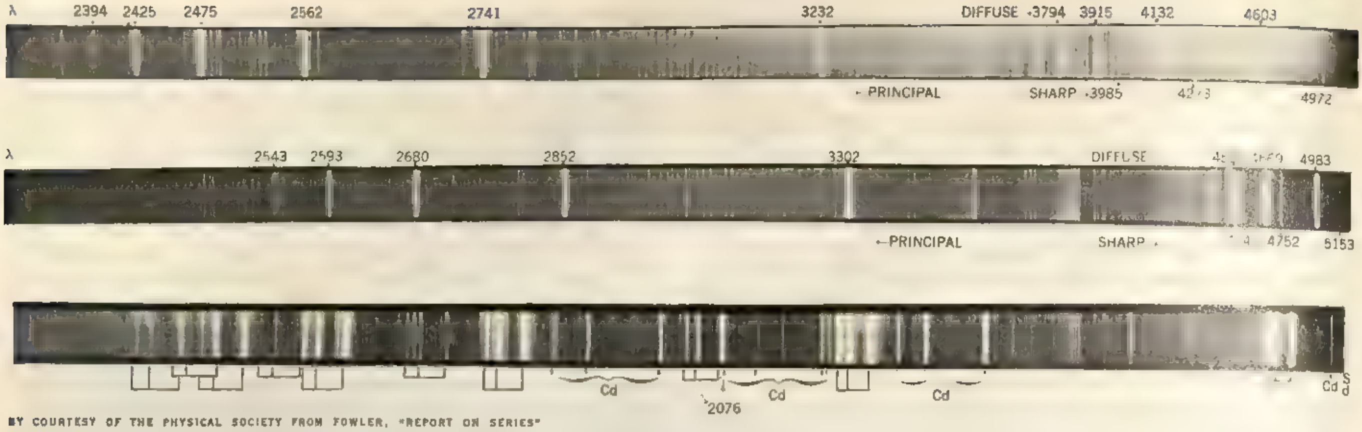
In terrestrial laboratories the application of spectroscopy to chemical analysis has always had to compete with conventional chemical methods; and progress was slow until precise photographic photometry was introduced about 1925, whereupon quantitative spectrochemical analysis quickly became common practice throughout the world. It is readily observed that when one element is progressively diluted in another, the spectra of the diluted element become progressively weaker and simpler until they finally vanish when the concentration is less than the limit of spectroscopic detection. Under specified conditions of observing, these partial or residual spectra may be correlated with the known composition of synthetic mixtures or standards and thus provide criteria for the quantitative estimation of comparable unknowns. This is essentially the principle of spectrochemical analysis as first applied to solutions by W. N. Hartley about 1880, to fused salts by A. de Gramont about 1900, and to metal alloys after about 1920. In 1925 W. Gerlach showed that unavoidable fluctuations in light sources and spectrum photography could be largely eliminated by referring the intensity of an impurity line to a neighbouring line of the major component as standard.

In the spectrum of any alloy or mixture of known composition, one or more pairs of lines can usually be found in which a strong (analysis) line of a minor constituent has the same intensity as a weak (internal standard) line of the major constituent. When such homologous pairs are found in spectrograms of samples containing different but known amounts of the analysis element, the concentration of this element in other samples is found by intercomparing the line pairs and selecting the one in which the two lines are of equal intensity. A further improvement of this internal-standard method resulted from the use of only one pair of lines the relative intensities of which in known samples are determined by photometric measurements and plotted as a function of concentration of the analysis element. If the two variables are plotted on logarithmic scales, the resulting analytical curve is usually a straight line with slope about one. After the preparation of such a calibration graph for each analysis element, any sample of comparable composition is easily analyzed by measuring line-intensity ratios and reading concentrations from the graphs. An excellent description of the preparation of samples and standards, spark excitation of spectra, and analytical procedure can be found in *Spark Spectrographic Analysis of Commercial Tin*, published (1942) as Research Paper 1,451 of the National Bureau of Standards.

Similar procedures have been perfected for the analysis of iron alloys, aluminum alloys, magnesium alloys, brasses, bronzes, type-metal, and practically all other types of metallic compounds. Careful chemical calibration and photographic photometry have reduced routine analytical errors to 1% or 2% of the amount present, and the time required for a complete analysis of a sample has been reduced to ten minutes or less. Since most of the time required for such an analysis is consumed in procuring and measuring a photographic spectrogram, elaborate spectrographs have been constructed with 55 photoelectron multiplier tubes to receive light from an internal standard line and from 54 different analysis lines. Radiant energies received by these phototubes are amplified to actuate indicators calibrated in percentage composition, thus permitting simultaneous and almost instantaneous determination of 20 to 35 elements. For composition control of metals and alloys in production, spectroscopy has surpassed chemistry in speed, sensitivity, and accuracy of analysis. It must be remembered, however, that no satisfactory absolute method of spectrochemical analysis had been devised; all the practical methods in the 1960s were relative to synthesized standards or chemically analyzed samples that served for spectrographic calibration.

Emission spectroscopy has also found extensive application to analytical problems in agricultural, biological, and pathological chemistry, in mineralogy and geochemistry, and in archaeology and criminology. In these problems the samples are often in liquid or powder form that can be vaporized and excited to emit spectra either in hot flames or in electric arcs or sparks between electrodes of pure carbon. Usually a definite amount of some suitable element is added to supply internal standards, and then the calibration and analytical procedures are essentially the same as for solid metal samples.

Empirically, it is found that, operating with light sources at atmospheric pressure and with spectral detectors sensitive between



BY COURTESY OF THE PHYSICAL SOCIETY FROM FOWLER, "REPORT ON SERIES"

2000 and 9000 Å, at least 70 chemical elements can be readily determined by emission spectroscopy. This is related to the fact that these elements have ionization potentials less than ten volts and their strongest lines have wavelengths between the limits mentioned. Gaseous elements have higher ionization potentials; their strongest lines are in the far ultraviolet, and their spectra are fully developed only at reduced pressure in Geissler tubes. In principle, every one of the 103 chemical elements known in the 1960s can be detected and determined by means of emission spectra (*see* SPECTROCHEMICAL ANALYSIS).

Structure of Spectra and of Atoms.—Because atomic spectra appear, generally, to consist of a random distribution of lines of different intensities, a century elapsed between the discovery of spectral lines by Fraunhofer and a fruitful clue to their physical interpretation by Niels Bohr (1913). Then in little more than a decade an amazing development in analysis and theory of spectral structure made all spectra interpretable in terms of atomic properties and, conversely, permitted the deduction of atomic structure from observations on spectra.

Hydrogen is the lightest atom and possesses the simplest spectrum; in the visible it consists of a regular succession of lines with ever closer spacing and decrement of intensity in the direction of shorter wavelengths. In 1885 J. J. Balmer discovered an extremely simple mathematical relationship between these H lines. Expressed in wave numbers the Balmer formula gives $\nu = R/2^2 - R/n_1^2$, where the constant $R = 109{,}678.76$ cm.$^{-1}$, and n_1 represents the integers 3, 4, 5 . . . ∞. This Balmer series begins with 6562 Å and ends at 3646 Å. Similar H series were later found in the extreme ultraviolet, $\nu = R/1^2 - R/n_1^2$, by T. Lyman, and in the infrared, $\nu = R/3^2 - R/n_1^2$, by Paschen. All possible H series can be accurately represented by one formula, $\nu = R/n_2^2 - R/n_1^2$, where n_2 and $n_1 > n_2$ are integers and n_2 is constant for a given series. Thus, the wave number of any H line can be expressed as the difference of two quantities, the larger being a constant term called the limit of the series, whereas the other varies from line to line and is known as the running term.

MULTIPLETS OF NEUTRAL AND IONIZED ATOMS WITH SIX-PLACE WAVE NUMBERS FOR SOME LINES: ALTERNATION LAW ILLUSTRATED VERTICALLY, DISPLACEMENT LAW HORIZONTALLY

In 1889 J. R. Rydberg reported finding series in the spectra of alkali and alkaline earth elements, and, notwithstanding the imperfect data then at his disposal, he discovered most of the important properties of spectral series. From certain characteristics of the lines, he distinguished three species of series (principal, sharp, and diffuse) superposed in the same spectrum, and he recognized that the members of each series were double for alkalis (Li, Na, K) and either single or triple for alkaline earths (Mg, Ca, Zn). Rydberg found that each series could be represented in wave numbers by a formula of the type $\nu = L - \frac{R}{(m+\mu)^2}$, in which L is the limit of the series, R the Rydberg constant (practically identical with R in the Balmer formula), and m has successive integral values to which a constant fractional part μ is added. A fourth type of series was discovered in 1907 by A. Bergmann, and because it was more hydrogenlike ($\mu \approx 0$) than the others, it came to be called fundamental. Rydberg also indicated that the difference between the limit of the P series and the common limit of the D and S series is equal to the wave number of the first line of the P series, and C. Runge in 1908 pointed out a similar relation between the D and F series, so that all the different series were interconnected. An abbreviated notation was then adopted for the four basic types of series:

Principal	$\nu = n\,\mathrm{S} - m\,\mathrm{P}$
Sharp	$\nu = n\,\mathrm{P} - m\,\mathrm{S}$
Diffuse	$\nu = n\,\mathrm{P} - m\,\mathrm{D}$
Fundamental	$\nu = n\,\mathrm{D} - m\,\mathrm{F}$

where n stands for a simple integer, and m for appropriate integers plus μ. In order to distinguish the components of doublets and triplets from each other, it was necessary to add subscripts to these term symbols. In addition to the regular series, others were detected when the limits were changed and still others between singlet and triplet terms (Ritz combination principle). Thus, it appeared that any given term might combine with many others, and although two terms were necessary for each observed line, the total number of terms required to represent any spectrum completely might be much smaller than the total number of lines.

In 1914 A. Fowler found ionized helium atoms (He^+) characterized by a hydrogenlike series except that the Rydberg constant R required multiplication by 4. He also discovered, in the spark spectra of Mg^+, Ca^+, and Sr^+, series of doublets resembling the P, S, and D doublets of alkalis but with 4 R in their formulas. By

1919 the regularities detected in various spectra sufficed to suggest two general laws: (1) the alternation law, which states that even and odd multiplicities of terms alternate in successive columns of the periodic system; and (2) the displacement law, which states that the spectrum of an ionized element resembles that of the neutral element preceding it in the periodic system. Term multiplicities of atoms or ions are thus determined solely by the number of electrons, whereas the atomic charge affects the position of the spectrum. These facts suggested a direct connection between spectral lines and the electrons and protons in atoms.

In 1913 Bohr proposed two fundamental postulates, viz., that atomic stationary states exist, and that the radiation frequency is equal to the energy difference of two states divided by Planck's constant ($h = 6.6256 \times 10^{-27}$ erg sec.). The empirically established spectral terms must, therefore, be interpreted as quantized stationary energy states characteristic of atoms and ions. The rapid development of the quantum theory of radiation constitutes one of the most thrilling chapters in the history of science (*see* QUANTUM MECHANICS).

Quantum Numbers and Atomic Energies.—Omitting further review of historical and experimental details, the following discussion is restricted to a vector model of the Rutherford-Bohr atom (*see* ATOM), which is assumed to consist of a tiny but massive nucleus (composed of protons and neutrons) around which circulate one or more electrons. The maximum number of electrons in any atom is expressed by its atomic number Z (identical with the number of protons in its nucleus), and this number ranges from 1 for H, the lightest, to 103 for Lw, the heaviest known in the 1960s. These electrons move in imaginary orbits about the nucleus at average distances represented by a principal quantum number n, which in turn numbers the successive shells of the periodic system and serves as a coefficient to the term symbol S, P, D, F. . . . A sequence of n term values subtracted from a limiting term gives the wave numbers of lines in a spectral series. In most cases an electron jump from one shell or value of n to any other shell or value of n constitutes the largest change in energy that can occur in a given atom. If an electron is moved from its lowest value of n to $n = \infty$, the atom is ionized, and the energy required to accomplish the removal of an electron is called the ionization potential. This energy is usually expressed either in wave numbers (cm.$^{-1}$) or in electron volts (ev); in the case of H it is 109,678.76 cm.$^{-1}$ (the Rydberg constant) or 13.595 ev. (*See* Table VII.) Hydrogenlike spectra are also emitted by ionized helium He^+, by doubly ionized lithium Li^{2+}, by trebly ionized beryllium Be^{3+}, etc., but the spectra are shifted successively toward higher frequencies because the energy of electron orbits as a function of n is proportional to Z^2/n^2. It follows that for He^+ the separation energy of the remaining electron from the lowest level (the ionization potential) will be 4 times that for the H atom; for Li^{2+} it will be 9 times as great and for Be^{3+} 16 times.

MULTIPLETS

The next largest change in atomic energy (after that due to a change in n) is usually that associated with a constant orbital angular momentum of the optical electron. This momentum is pictured as a vector of magnitude 0, 1, 2, 3 . . . in $h/2\pi$ units; it is called the azimuthal quantum number and is symbolized by l. The numerical values of $l = 0, 1, 2, 3$ . . . correspond respectively to the empirical term symbols S, P, D, F . . . originally abbreviated from the different types of series first found in the spectra of alkali atoms. Electrons with $l = 0$ are called *s*-electrons; those with $l = 1$, *p*-electrons; those with $l = 2$, *d*-electrons; and those with $l = 3$, *f*-electrons. It may be interjected here that these four l values and the first seven n values suffice to describe the normal electron configurations of all possible atoms and ions. When two or more optical electrons are present, their individual orbital momenta, l_1, l_2, . . . are added vectorially to form a resultant L, but quantum theory dictates that such a resultant, as well as the individual l, can only exist as an integral multiple of $h/2\pi$. The individual l_i can, therefore, be oriented only in certain discrete directions to one another. For the case of two electrons with l_1 and l_2, the possible resultant L values are: $L = (l_1 + l_2)$, $(l_1 + l_2 - 1)$, $(l_1 + l_2 - 2)$ . . . $|l_1 - l_2|$. The vector addition for this case is shown graphically in fig. 13. If all but one of the l_i are zero, the resulting L will be identical with that one l_i. When there are three electrons for which $l \neq 0$, the vector addition is simply performed by combining the l values of two electrons and then combining each of the resulting L values with the l of the third electron. The term types given by various simple electron configurations are shown in Table I.

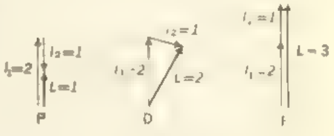

FIG. 13.—VECTOR ADDITION OF ORBITAL ANGULAR MOMENTA

$l_1 = 2$ and $l_2 = 1$ to give resultants $L = 3, 2, 1$

Quantum theory and observation show that an important selection rule controls atomic energy changes resulting in radiation, viz., the greatest intensity of emission results when $\Delta L = \pm 1$. In addition, when the interaction of the electrons is small, only

TABLE I.—*L Values and Term Symbols Arising from Various Simple Electron Configurations*

those quantum transitions take place for which only one of the electrons alters its l value in accordance with the selection rule $\Delta l = \pm 1$. Notwithstanding these simple rules, many spectra exhibit lines corresponding to $\Delta L = 0, \pm 2, \pm 3$, as well as to double-electron jumps.

MULTIPLETS

A third contribution to the total energy of an electronic system comes from the rotation of each electron about its own axis. This axial angular momentum has the same magnitude for each electron, $s = \frac{1}{2}(h/2\pi)$; it is usually called the electron spin. When two or more electrons are present, the individual spin vectors s_i combine with each other to yield a resultant S (just as the l_i combine to form L). Analogous to L, the resultant spin S can take only certain discrete values, the maximum being obtained when all the s_i are parallel, and the minimum being one-half or zero according as the number of electrons is odd or even.

The spinning electrons and their resultant spin vectors S account for the splitting of most spectral terms into two or more components and provide a physical meaning for the subscripts (inner quantum numbers) originally attached to components of polyfold terms. The total angular momentum J of an atom is the vector sum of the resultant orbital angular momentum L and the resultant axial angular momentum S. According to quantum theory, L and S can be oriented to each other only in certain directions, and, therefore, only certain discrete values of the resultant J are possible. The largest and smallest values of J result from simple addition and subtraction of L and S, while all inter-

mediate values that differ by integral amounts are allowed; *i.e.*,

$$J = (L+S),\ (L+S-1),\ (L+S-2),\ \ldots\ |L-S|$$

This rule is illustrated graphically for simple cases in fig. 14. When $L > S$, it is obvious that the number of permitted J values for a given value of L is $2S+1$. On the other hand, if $L < S$, the number of permitted J values for a given L is $2L+1$. Thus, for S terms ($L = 0$, $2L+1 = 1$) there is only one value of J; *i.e.*, $J = S$. Similarly, for P terms ($L = 1$, $2L+1 = 3$) the number of components can never exceed three. However, for a great majority of terms $L > S$, and for all these the possible number of components or term multiplicity r is equal to $2S+1$. The empirically indicated alternation law follows directly from this result, since the maximum multiplicity will be even or odd according as the number of electrons is odd or even.

In general, atomic energy states with different S are not expected to combine with one another because of a selection rule $\Delta S = 0$, but intersystem combinations are found to be fairly abundant and intense, especially as the atomic number increases. Table II displays the resultant S values and possible multiplicities for different numbers of electrons.

The total angular momentum of an atom can have integral or half integral $J(h/2\pi)$ values because $s = \frac{1}{2}(h/2\pi)$ for each electron. Furthermore, different sets of J values are associated with the same type of term (same L value) in systems of different multiplicity because S is different. And finally, different sets of J values apply to different terms in the same multiplicity system because $J = L + S$. Since J represents the total angular momentum, it is the most important quantum number for the fine structure or multiplet analysis of atomic and ionic spectra. It has a perfectly definite physical meaning and quantitative value under all circumstances. Atomic energy changes are rigorously regulated by the simple selection rule that $\Delta J = 0, \pm 1$, except that all 0 to 0 transitions are prohibited. Since the a priori probability that an atomic energy state exists is expressed by its statistical weight $2J+1$, it is obvious that J is important for the relative intensities of spectral lines. The J values that belong to a few different spectral terms in different multiplicity systems are shown in Table III.

For any given spectrum in which energy levels have been established, relative values of J attached to the levels are readily determined from their combining properties and the selection rule $\Delta J = 0, \pm 1$. In spectra resulting from terms of odd multiplicity the absolute value of J is fixed by the absence of the transition $J = 0$ to $J = 0$, which is forbidden. In other cases, the absolute value of J can be deduced from the multiplicity and type of term if these are unambiguous as, for example, in multiplets that are sufficiently law abiding so that the terms can be identified from the sum rule (the sum of the intensities of all the lines of a multiplet that belong to the same initial or final state is proportional to the statistical weight $2J+1$ of the initial or final state, respectively) or from the interval rule (the interval between two successive components, J and $J+1$, of a polyfold term is proportional to $J+1$). Analysis of the more complex spectra is usually hopeless without the aid of Zeeman effect; *i.e.*, the splitting of the

lines into polarized components when the source of light is placed in a strong magnetic field. The total angular momentum J is space quantized in a magnetic field and can assume $2J + 1$ discrete values, which are differentiated by magnetic quantum numbers M. The magnitude of the level splitting is the same for all singlet levels (normal Zeeman effect) but differs for all other terms according to the values of L and J (anomalous Zeeman effect). From any completely resolved Zeeman pattern the J values of the two combining levels are deduced at once from the number of components, and the L values are simultaneously derived from the separations of the components, since the splitting factors have been accurately given empirically and by the quantum theory (*see* Zeeman Effect).

Summarizing the above discussion of quantum numbers recalls that any atomic energy level (spectral term) is completely specified by four quantities: (1) its principal quantum number n, which indicates the electron shell or period that the optical electron occupies; (2) its type—S, P, D, F . . . where the capital letters stand for azimuthal quantum numbers or orbital angular momenta $L = 0, 1, 2, 3$ . . . respectively; (3) its inner quantum number or total angular momentum J (written as a suffix or subscript to the term type symbol); and (4) its multiplicity number $r = 2S + 1$, written as a superior prefix to the term type symbol. Thus 4^3D_2 represents the middle component ($J = 2$) of a D term ($L = 2$) in a triplet system ($r = 3$) for which the principal quantum number $n = 4$. Theoretically, the energy difference of two terms appears as intense radiation only when $\Delta L = \pm 1$, $\Delta J = 0, \pm 1$, $\Delta r = 0$, and the two terms are of opposite parity; *i.e.*, odd and even (Laporte rule). Typical energetic relationships of spectral terms and combining properties of the levels are shown graphically in fig. 15, which represents the spectrum of neutral mercury atoms.

Pauli Exclusion Principle.—Having found an electronic-quantum interpretation of spectral terms, it is next in order to seek the connection between spectral terms and atomic structure. In order to understand the development of the periodic system (*see* Periodic Law) and to account for striking periodicities in atomic properties, it is necessary to introduce a new assumption, known as the Pauli exclusion principle, which states that: "in one and the same atom, no two electrons can have the same set of values for the four quantum numbers, n, l, m_l, and m_s." Table IV shows the electron shells and subgroups that are possible for atoms as a consequence of this exclusion principle. The n cells are divided by l, and the l cells are further divided by m_l and by m_s, but, instead of inserting the last quantum numbers, the presence of an electron in a (n, l, m_l) cell is represented by arrows pointing up or down according as m_s is $+\frac{1}{2}$ or $-\frac{1}{2}$. Only two electrons can be in each such cell, and then only when they have antiparallel spin directions, since otherwise these two electrons would have the same four quantum numbers n, l, m_l, m_s. The maximum number of electrons that can have the same n and l is given by the number of arrows in the corresponding cells. This number is equal to $2(2l + 1)$, since $2l + 1$ is the number of possible m_l values

etc.	

for a given l. Thus, in any one shell no more than 2 s electrons (s^2), 6 p electrons (p^6), 10 d electrons (d^{10}), and 14 f electrons (f^{14}) can exist, and summing these numbers successively gives 2, 8, 18, and 32, which are precisely the totals of elements found in successive groups of atoms exhibiting periodic properties when arranged in atomic number sequence. Naturally the electron configurations of atoms in their lowest possible energy states, and the corresponding spectral terms, will show a periodicity, since, after a certain number of electrons of a given type have been added, the outermost electron will be once more, for example, an s-electron.

The spectral terms describing ground states of atoms may be deduced from assumed electron configurations by adding together the l and s moments of the individual electrons, but first it is necessary to make an assumption about the mutual coupling or interaction of the individual vectors. The coupling that seems to be most common is called LS coupling, expressed as

$$(l_1, l_2, \ldots) \ (s_1, s_2, \ldots) = (L, S) = J$$

This means that the individual l_i vectors are strongly coupled to produce resultant L values of different energies, and the individual s_i vectors are also strongly coupled to produce resultant S values of different energies. The resultants L and S are then less strongly coupled with one another, and their resultant is J. Other types of electron coupling, in particular jj coupling, occur relatively rarely, but coupling intermediate between LS and jj is found more frequently, especially among excited states of heavy elements. However, because LS coupling applies to all the lighter elements, predominates in many others, and is either accurately or very approximately valid for the ground states of all atoms and ions, it forms the basis for the standardized notation for spectral terms.

The spectral terms arising from nonequivalent electrons (belonging to different n, l groups of Table IV) may be obtained in simple cases by adding the L values of Table I to the S values of Table II. For example, two nonequivalent p electrons pp yield ($L = 0, 1, 2$) S, P, D terms, and since the electron spins can be either antiparallel or parallel ($S = 0, 1$), there will be singlet and triplet terms ($r = 2S + 1$); *i.e.*, pp always produces a family of terms ^1S, ^1P, ^1D, ^3S, ^3P, ^3D. Examples of the term families invariably associated with certain pairs or triads of nonequivalent electrons are given in Table V.

When two electrons are equivalent, *i.e.*, have the same n and the same l, they must at least differ in their values of m_l or m_s. For example, when two equivalent p-electrons (p^2) have l with the same direction (giving a D term), m_l is the same ($+1, 0, -1$) for both, and, therefore, both cannot have $m_s = +\frac{1}{2}$, or both $m_s = -\frac{1}{2}$. This means that their spins can only be antiparallel for a D term, thus producing ^1D but not ^3D. Altogether two equivalent p-electrons (p^2) can produce only the terms ^1S, ^1D, ^3P, whereas

etc.	

two nonequivalent p-electrons (pp) yield ^1S, ^1P, ^1D, ^3S, ^3P, ^3D. Other examples of terms identified with equivalent electrons are displayed in Table VI.

An important consequence of the Pauli principle is that closed shells (in which the maximum number of equivalent electrons is present) have $L = 0$ and $S = 0$ and, therefore, always present the $^1S_0$ state. Closed shells can, therefore, be ignored when deriving the terms given by any electron configuration. Furthermore, $^1S_0$ for a closed shell must result when the shell is divided into two parts, the term types for each part derived, and the resulting angular momentum vectors added together. For example, adding the angular momenta of p^2 electrons to the corresponding quantities for p^4 electrons will give the resultant for p^6 electrons; *i.e.*, $^1S_0$. From this it follows L and S must be the same for these two electron configurations, and the terms arising from p^4 are the same as those from p^2. Similarly, d^6 gives the same terms as d^4, f^{12} the same as f^2, etc. In general, any subgroup lacking one or more electrons to fill the group behaves spectroscopically as if the lacking electrons alone were present, except that the terms are regular (smallest J level has least energy) when the group is less than half filled but inverted when more than half filled.

Finally, of the terms given by equivalent electrons, those with greatest multiplicity generally lie lowest, and of these the lowest is that with the greatest L. In Table VI the last listed term is the lowest energy in each family.

Normal States and Electron Configurations of Atoms.—Quantum principles having thus specified the types of spectral terms arising from certain electrons, it became theoretically possible in 1925 to determine from identified spectral terms the electron configurations of all atoms and their ions. By 1964 the ground states of 96 atoms had been uniquely determined from spectral structure, and since these data are of great importance in spectroscopy, atomic physics, and chemistry, they are collected in Table VII. In addition, Table VII lists all the spectral multiplicities experimentally detected, all the reported spectroscopic ionization potentials, and the wavelengths of the strongest spectral lines characteristic of neutral atoms. In general, the strongest lines result from $s \leftrightarrow p$ electron transitions.

Hyperfine Structure of Spectral Lines and Properties of Atomic Nuclei.—When examined with apparatus of adequate resolving power, many spectral lines have been found to consist of two or more components lying extremely close together. This hyperfine structure arises from properties of the atomic nucleus

with which optical electrons interact more or less according to their orbits. The actual line splitting is exceedingly small (usually a fraction of a wave number) but nevertheless of very great importance because it provides a means of obtaining quantitative information about certain properties of isotopic nuclei. The spectroscopic influence of a nucleus may arise from its mass or from an intrinsic angular momentum or nuclear spin, analogous to electron spin. The former is called isotope effect and the latter nuclear-spin hyperfine structure, or *hfs* for short.

Isotope Effect.—Many natural elements consist of a mixture of two or more isotopes, each of which has an approximately whole number atomic weight. Different isotopes of an element have the same number and arrangement of outer electrons and, consequently, have the same multiplet structure for their spectra. They are, however, distinguished from each other by their mass because an electron necessarily revolves about the common centre of gravity of itself and the nucleus, and the Rydberg constant, therefore, depends on the nuclear mass. Thus, the Balmer lines of $1H^1$ atoms are accompanied on the short-wave side by very faint companions ascribed to $1H^2$, and the detection of these isotope-effect components in 1932 constituted the discovery of heavy hydrogen. Similar isotope effects have been observed in many other spectra, but as soon as several electrons are present, the simple mass effect observed in the hydrogen spectra is complicated by other factors that were not completely understood in the 1960s.

Nuclear-Spin Hyperfine Structure.—True *hfs* can be simply and quantitatively explained if it is assumed that the nucleus of the emitting atom possesses an angular momentum and an associated magnetic moment. According to quantum theory, the nuclear spin can be only an integral or half-integral multiple of $h/2\pi$. It is written $I(h/2\pi)$, where I is the spin vector or quantum number of the nuclear angular momentum. The spectrum of the H_2 molecule shows that for the simplest atomic nucleus (the proton) $I = \frac{1}{2}$. The proton thus has the same mechanical moment as the electron, but various values may be expected for heavier nuclei, since they contain more than one proton. As with electron spin, a magnetic moment is associated with the nuclear spin, since the nucleus is electrically charged and the rotation of electrically charged particles gives rise to a magnetic moment. Because a proton is the same size as an electron but 1,840 times heavier, the magnetic moment of an atomic nucleus is always 1,000 to 2,000 times smaller than that of an electron. For this reason the spectral term-splittings (energy differences) deduced from *hfs* are usually less than 1/1,000 those in multiplet structure (*see* NUCLEAR MOMENTS).

In the same way that (for multiplet structure) L and S were combined to obtain the total angular momentum J of the optical electrons, it is necessary (for *hfs*) to combine J and I in order to obtain the total angular momentum F of the whole atom, including nuclear spin. The hyperfine quantum number F can take the following values: $F = J + I, J + I - 1, J + I - 2, \ldots, |J - I|$. This gives, in all $2J + 1$ or $2I + 1$ different values, according as $J < I$ or $J > I$. The vector-addition diagrams for J and I will be identical with those for L and S where $J = L$ and $I = S$ (*see* fig. 14). In general, the number of *hfs* components of a spectral term is different for different terms of the same spectrum. Terms with $J = 0$ are always single, but all others terms are split into two components if $I = \frac{1}{2}$. If I is greater than $\frac{1}{2}$, terms with $J < I$ have $2J + 1$ components, whereas those with $J > I$ have $2I + 1$ components.

The magnitude of hyperfine splitting depends on the nuclear magnetic moment but is also dependent on the type of electron. Thus, spectral terms arising from electron configurations containing one s-type electron will be split wider than those from a p electron with the same principal quantum number, because the s electron approaches closer to the nucleus and undergoes a stronger interaction. The transitions between *hfs* states are regulated by the same selection rule for F that holds for J, *i.e.*, $\Delta F = 0, \pm 1$, but 0 to 0 transitions are forbidden. Furthermore, the same intensity rule and the same interval rule are valid for both *hfs* and ordinary multiplet structure, except F replaces J.

After deriving (from spectroscopic observations and quantum theory) a satisfactory explanation of *hfs*, it became possible conversely to deduce, from the results of spectroscopic experiments, several properties of atomic nuclei. In 30 years following 1927, the mechanical moments or spins of 226 atomic nuclei were determined, the magnetic moments for 194 and the quadrupole moments for 75. The results are compiled in *Progress in Nuclear*

Physics, vol. 6 (1957). Typical data are shown in Table VIII in which the exponent on the chemical symbol represents the mass of the atomic nucleus. In general, nuclear mechanical moments are derived either from the number of observed *hfs* components, or from their relative intensities, or from the intervals between *hfs* levels. Magnetic moments are calculated from a theoretical formula containing the observed *hfs* intervals and other constants, but the most precise values have been obtained from measured deviations of atomic or molecular beams in inhomogeneous magnetic fields. A positive moment indicates that the *hfs* terms are regular; *i.e.*, the level with smallest F value has the lowest energy. Deviations of *hfs* levels from the interval rule are referred to a quadrupole moment arising from a nonspherical distribution of protons in the nuclei. There are two possibilities: if the positive charge is spread in the direction of the mechanical moment, the nucleus is elongated and has a positive quadrupole moment; otherwise the nucleus is flattened and has a negative quadrupole moment.

The only regularity apparent in Table VIII is that the nuclear mechanical moment is a half integer if the mass of the nucleus is odd, and a full integer if the mass is even. It is also seen that the algebraic sums of the mechanical moments and of the magnetic moments of the neutron (n) and proton (H^1) are exactly and nearly equal, respectively, to the same quantities for the deuteron (D^2).

The manner in which the moments of the elementary particles must be combined to yield the observed values for the other atomic nuclei has been partially explained by a nuclear shell model (*see* NUCLEUS: *Nuclear Structure and Nuclear Forces*). *See* also references under "Spectroscopy" in the Index.

SPECTROSCOPY, ASTRONOMICAL, is a branch of astrophysics based on information obtained by means of a prism, a diffraction grating, or some other light-dispersing device. By using such techniques data have become available that make it possible to identify the chemical elements present on the sun and other stars. In a widely celebrated series of investigations, for example, the element helium was detected on the sun about a generation before its presence on earth was demonstrated. Application of spectroscopic methods to the problems of astronomy permits indirect measurements to be made of the temperature of far-distant stars. Astronomical spectroscopy also revealed the phenomenon of the red shift. This is an application of the Doppler effect in regard to the wavelengths of electromagnetic radiation and manifests itself in spectroscopy by a shift of a light source's spectral lines toward the red end of the spectrum. The identification of this phenomenon provided a basis for the theory of the expanding universe (*see* COSMOLOGY).

This article is organized into the following sections and subsections:

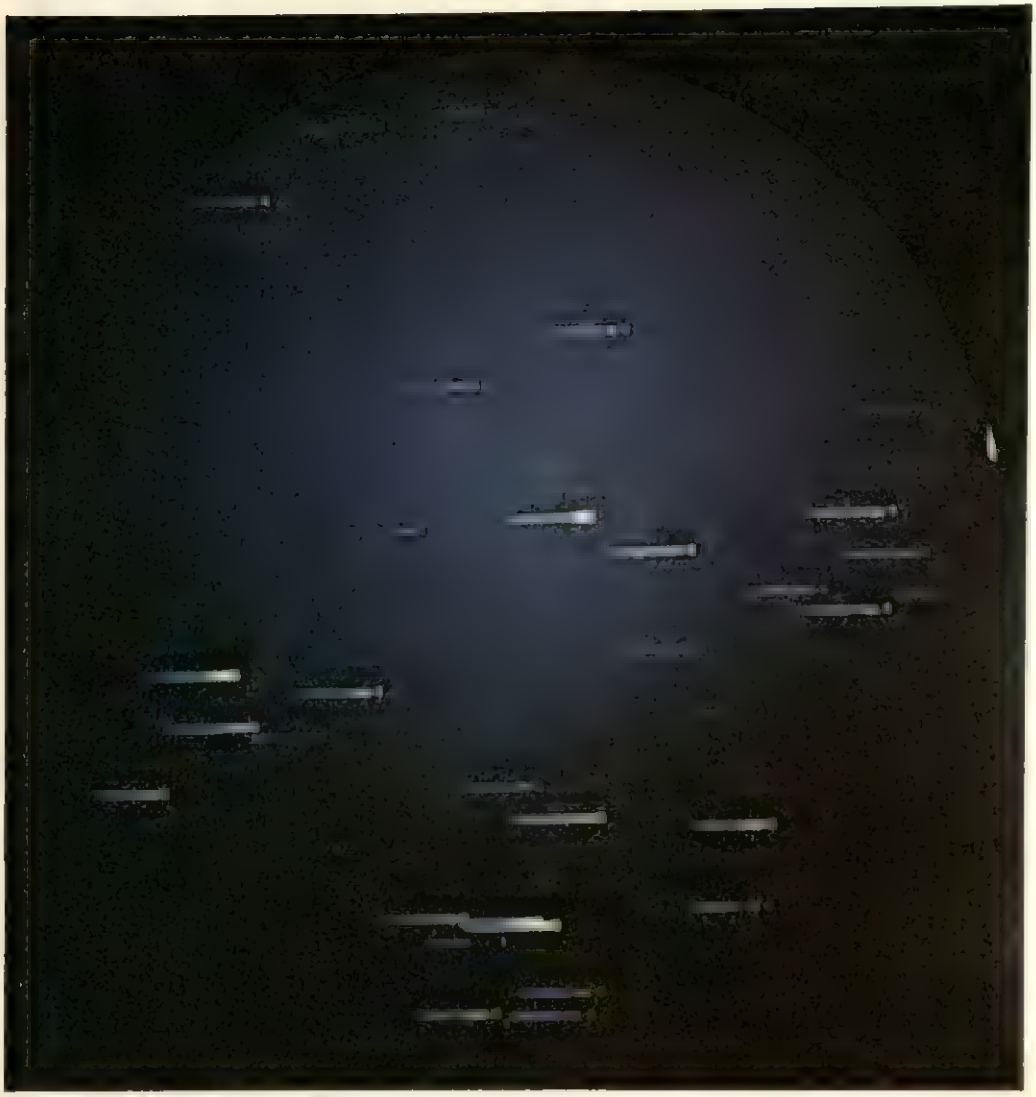
I. HISTORICAL DEVELOPMENT

Astronomical spectroscopy had its beginning in 1666 when Isaac Newton observed the separation of the colours of the rainbow in a prism. In 1802 William H. Wollaston placed a narrow slit in a window blind and with a prism of better quality than the one used by Newton, but without a collimator or a camera, noticed several dark lines in the spectrum of sunlight. Real progress in astronomical spectroscopy became possible when Joseph von Fraunhofer in 1814 made use of a telescope, in addition to the prism and a distant slit, and thereby constructed the first modern spectroscope. A collimator lens was first used by W. H. Simms in 1840. With his instrument Fraunhofer observed and mapped 754 dark lines in the spectrum of the sun. He also observed the spectra of several bright stars and found that, although they all had dark lines upon a coloured continuum, the lines were not the same as those of sunlight. Fraunhofer noticed that the yellow emission line from a flame fed with table salt, which had already been observed by John Herschel, coincides in position with a conspicuous black line in the solar spectrum, which he had designated by the letter D. But he did not follow up this result.

It was only after Gustav R. Kirchhoff had advanced his famous

three laws of spectroscopy that the connection between absorption and emission became obvious (*see* SPECTROSCOPY: *History*). Thereafter William Huggins (1824–1910) in England undertook a systematic survey of the spectra of all stars and nebulae within the reach of his instruments at Tulse Hill in London. This period was the richest in the number and importance of astrophysical discoveries. Many different types of stellar spectra were found; the Orion nebula was found to be gaseous, contrary to the opinion of other astronomers, while the Andromeda nebula showed a continuous spectrum similar to that of normal stars like the sun. Huggins concluded independently of Johann K. F. Zöllner that the solar prominences could be observed without an eclipse by means of a spectroscope, and that the planets shine by reflected sunlight. He was the first to try to measure the radial motions of stars from the Doppler displacements of their lines.

The work of Huggins was of a pioneering character, and it was he who laid the foundations for all further investigations. His tradition in England was carried on by J. N. Lockyer and F. E. Baxandall at the Solar Physics Observatory in South Kensington, which was transferred to Cambridge after Lockyer's retirement in [illegible].



BY COURTESY OF THE UNIVERSITY OF MICHIGAN

SPECTRAL IMAGE OF STARS SEEN THROUGH A PRISM PLACED IN FRONT OF THE TELESCOPE LENS REVEALS IN RAINBOW COLOURS BOTH THEIR BASIC COMPOSITION AND THEIR TEMPERATURES. THIS STAR GROUP IS CALLED THE HYADES

The problem of spectral classification was undertaken in the middle of the 19th century by Angelo Secchi in Italy and was later continued by H. C. Vogel in Germany, who was the first to introduce the photographic method into spectroscopy, and who succeeded in determining accurate radial velocities of many stars. Vogel's work, especially his measurements of radial velocities, stimulated several other observatories, near the turn of the century, to undertake systematic studies in this field. W. W. Campbell at the Lick Observatory undertook the determination of the motions of all stars brighter than magnitude 5.5 in both hemispheres of the sky. E. B. Frost at the Yerkes Observatory concentrated upon the motions of hot stars. J. S. Plaskett at Victoria, British Columbia, discovered many spectroscopic double stars and determined their orbits; he also extended to fainter stars the work of other observatories. W. S. Adams and his associates at Mount Wilson Observatory, California, determined the velocities of hundreds of faint stars and increased the precision to about ±0.01 km./sec. in the case of the bright star Arcturus. A. A. Belopolsky at Pulkovo, Russia, and, more recently, G. A. Shajn at Simeis, in the Crimea, also made contributions in this field. H. Spencer Jones, then at the Cape Observatory, published numerous measures of stellar motions in the southern sky. C. Fehrenbach in France has developed a reliable method of determining stellar radial velocities on objective-prism (slitless) plates.

The work on spectral classification received a new impetus when E. C. Pickering at Harvard, assisted by Miss A. J. Cannon, Miss A. C. Maury, and Mrs. W. P. Fleming, undertook the classification of several hundred thousand stars over the entire sky. This work, culminating in the *Henry Draper Catalogue* by Miss Cannon, published 1918–24, provides the basis for all modern astrophysical work.

The spectroscopic study of the sun was advanced by P. J. C. Janssen, of the Meudon Observatory in Paris, who followed Huggins' suggestion and succeeded, in 1868, in observing the prominences of the sun in full daylight. Further advances were made by N. C. Dunér in Sweden, who determined the rotation of the sun from the Doppler effect (*q.v.*) and found it to be different in different latitudes of the sun, and by H. A. Rowland at Johns Hopkins University, who prepared a catalogue of solar wavelengths. At the turn of the century great progress in this field was made by G. E. Hale, who successively founded and directed the Kenwood Observatory in Chicago, the Yerkes Observatory in Williams Bay, Wis., and the Mount Wilson Observatory at Pasadena, Calif. The spectroheliograph was invented independently by Hale, and by H. A. Deslandres of the Paris Observatory. In 1908 Hale discovered the large magnetic fields in sunspots by observing the Zeeman effect (*q.v.*), the shift in the positions and shapes of the sunspots' spectral lines due to the interaction of the atoms with the magnetic field.

Of all the results of astronomical spectroscopy none is more interesting than the evidence for the uniformity of distribution of the chemical elements throughout the universe. It was a revelation to the earlier spectroscopists when they discovered, first in the sun and later in the stars and nebulae, the same familiar substances—hydrogen, iron, calcium, and the rest—that they knew on the earth. The belief in the universality of the chemical ele-

ments was much strengthened when the lines of helium, originally found in the spectrum of the rim of the sun in 1868 by P. Janssen and by J. Norman Lockyer, were first produced in terrestrial laboratories about 25 years later. It was only in 1941 that the last great enigma of line identification was solved when B. Edlén, in Sweden, announced that the previously unidentified lines of the solar corona originate in the atoms of the common elements, iron, calcium, nickel, and argon, excited to a degree of ionization not even dreamed of previously. Henry Norris Russell had remarked earlier, when Ira S. Bowen in a similar manner disposed of the so-called "nebulium" lines in certain nebulae, that the mysterious substances of the astrophysicists one after another literally disappeared in "thin air." As a matter of fact, Bowen found that the nebulae consist of oxygen, nitrogen, hydrogen, and a few other gases; in other words, they are not very different in composition from air.

The principle of the uniformity of chemical elements has now been extended to include even the distant galaxies, whose light travels hundreds of millions of years at the rate of 186,000 mi. per second before it reaches the eye of the observer. The principle of uniformity of chemical elements means that the atomic building blocks of the universe are the same throughout space. It does not mean that the proportions of these elements are the same in all astronomical objects. We know, in fact, that certain stars differ strikingly from others in their composition, and among the most pressing spectroscopic problems of today is the measurement of these differences in the abundances of elements. Such measurements permit the nuclear processes responsible for the formation of the elements to be inferred.

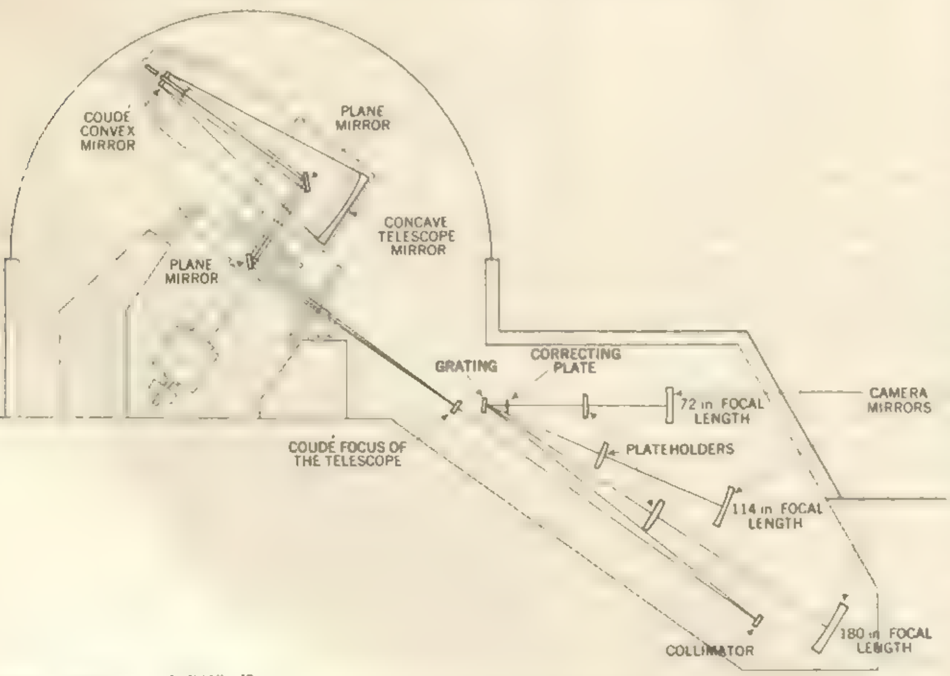
Many other applications of spectroscopy to astronomy, such as the measurement of the temperatures and the luminosities of stars, have developed so rapidly in recent years that their story can best be told separately in the sections that follow.

II. INSTRUMENTS

1. Slit Spectrograph.—The stellar spectrograph is an instrument constructed like an ordinary laboratory spectrograph (*see* SPECTROSCOPY: *Spectroscopes and Spectrographs*). But, since nearly all astronomical light sources are exceedingly faint, special precautions must be observed so that all the available light of the object be utilized in forming the spectrum. The instrument most commonly used is a slit spectrograph attached at the focus of an astronomical telescope. It is essential that the angular aperture of the collimator be the same as that of the telescope. Otherwise, light is spilled over the edges of the collimator (collimator of greater focal ratio than telescope), or the optical parts of the spectrograph are unnecessarily large and wasteful (collimator of smaller focal ratio than telescope). If the instrument is used in good seeing for the observation of stars, which appear nearly as points on the slit of the spectrograph, then the efficiency is proportional to the area of the telescope objective, while the purity is proportional to the length of the collimator. But, if the instrument is used for the observation of luminous surfaces, such as nebulae, the moon, the planets, etc., the efficiency is independent of the linear or angular apertures of the telescope and depends only upon the aperture of the collimator.

In practice the astronomer is usually concerned with intermediate conditions: the stars have tremor disks caused by irregularities in the air, and, while their images have a pronounced, sharp peak of light intensity in their contours, they cannot be regarded as mathematical points. Hence, it is advantageous to use a telescope of large aperture to gather in a large amount of light, and a long collimator to secure the maximum possible purity. In very "poor seeing," when the star images may be as large as ½ minute of arc in diameter (this would project as a disk of 4 mm. in diameter on the slit of the spectrograph of the 82-inch reflector of the McDonald Observatory), the advantages of the large aperture are largely lost, while in good seeing, when the diameter of the image is less than one second of arc, the efficiency is almost exactly proportional to the linear aperture.

For the greatest efficiency it is desirable to make the ratio of collimator to camera lengths as large as possible, so that the slit can be opened without increasing the width of the projected image of the slit on the plate to more than the size of the plate-grain clusters. Thus, short-focus cameras are favoured, which require dispersing units of great power in order to secure the desired scale of the spectrum. For ordinary work, with cameras having focal ratios in the order of $f/3$ to $f/5$, photographic lenses having three or four components give good results. For instruments of very short focus, microscope objectives were adapted successfully as camera lenses by W. B. Rayton and R. J. Bracey. The very fastest cameras, however, have usually been Schmidt cameras, those with twice-through corrector plates mounted directly in front of the gratings, as designed by I. S. Bowen at Mount Wilson and Palomar Observatory working down to about $f/1$. Even smaller focal ratios, extending to $f/0.35$, have been obtained with thick-mirror Schmidt cameras in which the photographic plate or film is pressed against the back of the corrector lens.



ADAPTED FROM A DRAWING BY T. DUNHAM, JR.

FIG. 1.—THE 70-IN. COUDÉ TELESCOPE SPECTROGRAPH

Slit spectrographs, mounted at either the prime focus or at the Newtonian or Cassegrain foci, move with the telescope and therefore must be made rigid enough to show no appreciable change in flexure during exposures lasting several hours. This difficulty is avoided in the fixed spectrographs mounted at the coudé focus of large reflectors, and in solar towers where coelostat mirrors send the light beam into underground shafts. Coudé spectrographs, similar to that sketched in fig. 1, are in use at the Mount Stromlo, Victoria, Lick, Mount Wilson, Palomar, McDonald, Okayama, and Haute Provence observatories.

For very bright objects long cameras and powerful dispersing units may be used. For example, the spectrum of the sun's surface has been photographed with the solar telescopes of the Mount

Wilson and Kitt Peak observatories with linear scales as great as 0.1 Å/mm. and resolutions up to 600,000. A few of the brightest stars also can be analyzed with such long cameras, but most stellar spectroscopy is carried out at much lower dispersions. While classification can be done with smaller scales, commonly from 40 to 250 Å/mm, radial velocities have usually been measured on plates having scales between 5 and 80 Å/mm. For very faint stars and intergalactic objects it has been necessary to work with scales as low as 500 to 1200 Å/mm.

The principal advantages of slit spectrographs consist of (1) greater purity than is possible with slitless instruments; (2) a comparison spectrum that can be photographed alongside the astronomical spectrum to serve in radial-velocity determinations; and (3) the elimination of the background of the night sky, which places a definite limit on the efficiency of slitless instruments.

The spectral region accessible to spectrographs on the surface of the earth is limited at the violet end by the absorption of the terrestrial atmosphere near λ (wavelength) 2900 Å. This limitation is dramatically removed by observations from rockets above the atmosphere. In 1946 the U.S. Naval Research Laboratory sent a spectrograph in a German V-2 rocket to a height of 33.5 mi. and photographed the sun's spectrum. Since that time the observations of the sun and a few of the brightest stars have been extended past the Lyman α line of hydrogen at λ 1216 Å and through the X ray region down to 1Å. On the long-wavelength end the practical limit set by the sensitivity of photographic emulsions or electron image tubes is about λ 12,000 Å (1.2 μ), but by using photoconductive cells of lead sulfide, mercury-germanium, etc., the observations in the far infrared have been extended out to 14 μ. Of course, there is atmospheric absorption in those regions also, due principally to bands of water vapour and carbon dioxide. Since molecules of the latter substances are most abundant in the lower part of the earth's atmosphere, it is possible to send telescopes and spectrographs suspended from balloons high enough to eliminate most of the terrestrial absorption. Spectra of planets and stars were taken at heights up to 16 mi. with the Stratoscope balloons of a group led by M. Schwarzschild at Princeton University, and planetary spectra of Venus and Mars were obtained by the balloon program of J. Strong at Johns Hopkins University.

The dispersing units of astronomical spectrographs are made in the form of prisms (glass, quartz, rock salt), or of diffraction gratings. The latter are particularly useful in the red and infrared regions, where the dispersion of glass is so low that a prohibitive thickness of the substance is required to obtain the same dispersion that a grating with 600 lines per millimetre gives in the second order.

The grating is also efficient in the ultraviolet region, where ordinary glass is opaque, and where quartz prisms are difficult to obtain in sufficiently large sizes for high-dispersion instruments. For rocket observations in the extreme ultraviolet below 800 Å, it is necessary to use the gratings at grazing incidence, which greatly enhances the reflectivity.

Although it has long been known that dispersion of light can be achieved by interference effects in a Fabry-Pérot etalon (a type of interferometer), the earlier astrophysical applications were directed mainly to the study of the auroral green line, which was photographed as early as 1922 by H. D. Babcock with a hand magnifier used as a camera lens. Because of the high resolution obtainable with a tunable etalon it is receiving increased attention, particularly for analysis of the solar spectrum in the infrared. Although the etalon can be used as a slitless device, it is generally combined with a conventional spectrometer.

In astronomical spectroscopy the photographic plate has reigned for many years as the most sensitive and convenient detector. Electronic enhancement of signal strength is now also used either to allow fainter spectra to be photographed, as in an image tube (electron camera), or to replace the plate by a photoelectric cell across which the spectrum is scanned. The increase in efficiency of an image tube is about a factor of ten as compared with direct photography.

Under ordinary observing conditions a large amount of light is lost on the slit jaws of the spectrograph (where it is used for

TWO TYPES OF SPECTRA

(Left) Spectrum of a rainbow, formed by refraction of sunlight in raindrops. (Right) A spectral photograph of the Ring nebula reveals the nebula as a series of coloured rings. The streaks in the picture are the spectra of nearby stars

guiding the telescope on the star image). It is not possible to filter this light into the spectrograph in such a way that it will reinforce the spectrum of the central portions of the star image. But an ingenious device has been constructed by Ira S. Bowen—an instrument called the image slicer—in which small plane mirrors are used to place the originally wasted light in the slit, alongside the main spectrum. In this manner a widened spectrum is obtained without letting the star trail on the slit, and this results in a substantial reduction of the exposure time.

2. Slitless Spectrograph.—The image of a star is approximately a point. Hence, if a prism is placed in front of the lens or mirror of a telescope, the spectrum is recorded as a narrow continuous band with interruptions in place of spectral lines. If during the exposure the star is permitted to trail slightly in a direction parallel to the refracting edge of the prism, a widened spectrum is obtained in which the star serves as its own slit. The great advantage of slitless spectrographs consists in the fact that they record a large field of stars in a single exposure instead of being limited to a single star on the slit of the instrument. The principal disadvantage lies in the fact that in a large telescope, such as would be required to record the spectra of very faint stars, the images of the stars are tremor disks of appreciable diameter, and spectra obtained in this way are not as pure as those of slit spectrographs.

Another difficulty lies in the absence of a comparison spectrum for determining the radial motions of stars. This can be circumvented by placing a cell filled with some absorbing solution in the path of the rays. Neodymium chloride has been used for this purpose, since it produces one sharp absorption band in the photographic region which can serve as a reference point for measuring the displacements of the stellar lines. A better standard of reference is furnished by the mean positions of the stellar lines themselves, if a direct and reversed image having the same dispersion can be produced side by side. This can be done by rotating the objective prism through 180° between exposures, but the difficult problem of constructing the rotating prism with sufficient mechanical and optical precision was not solved until 1947, when Charles Fehrenbach built his "normal-field prism" at Haute Provence. With improved versions of this instrument, Fehrenbach and his staff measured radial velocities of several hundred stars.

Most of the work on the spectral classification of faint stars is carried on with objective prisms. Although the earlier programs were done with photographic refractors, the wide field and critical definition of star images obtained with large Schmidt cameras has resulted in the general use of these telescopes for objective-prism work. Among the best-known Schmidt reflectors are the 24-in. of the Warner and Swasey Observatory at Cleveland, O., and the 32-in. of the Hamburg Observatory in West Germany.

3. Spectrophotometric Instruments.—For the measurement of the light intensities in continuous spectra and in spectral lines, microphotometers of various designs are used. Instruments for measuring spectrograms usually consist of a light source and a narrow slit; the latter—or its image—is placed in contact with the plate, parallel to the spectral lines, so that only a narrow band of light passes through the plate. This band falls upon a photoelectric

cell, which activates a galvanometer whose mirror produces a displaced light signal upon a sheet of photographic paper. As the plate is slowly moved across the slit, the drum carrying the paper is turned, and the signal produces a continuous record of the galvanometer deflection of the original beam, as modified by the continuous spectrum and by the lines on the plate. Tracings of spectra obtained in this manner must be calibrated by means of marks produced on the original plate by a step wedge, a tube sensitometer, or some similar device which changes intensities by known amounts. This is required in order to express the displacements of the signal on the tracings in terms of relative intensities. Several microphotometers have been designed to perform this wedge calibration automatically, and give tracings in which deflections are proportional to the intensities in the original spectrum.

The most accurate spectrophotometry is done directly at the telescope by mounting a second slit at the focus of the spectrograph and scanning the spectrum with a photoelectric cell. Scanners have been used extensively at both the coudé and Cassegrain foci of the Mount Wilson and Palomar reflectors.

4. Spectroheliograph.—Invented almost simultaneously in 1890 by G. E. Hale in Chicago and H. A. Deslandres in Paris, this is a large spectrograph into which a narrow slit has been built in front of the focal plane of the camera so that only the light of a narrow range of wavelengths falls upon the plate. This slit is so adjusted that the light of a particular absorption line in the sun's spectrum is transmitted. It must be remembered that the lines originate in the uppermost regions of the sun's atmosphere and are not completely dark but contain light of smaller intensity than that of the continuous spectrum. The continuous spectrum is formed by light which is produced, on the average, at a depth of several hundred kilometres in the atmosphere. The image of the sun is projected upon the first, the ordinary, slit of the spectrograph, and the entire telescope is slowly moved by means of an electric motor at right angles to the slit. Simultaneously the plateholder carrying the sensitive emulsion is moved past the second slit. An image of the sun thus is obtained on the plate which is produced by the residual light of a particular spectral line. Since not all regions on the surface of the sun are equally bright in such monochromatic light, it is possible to study features like calcium eruptions (or flocculi), hydrogen tornadoes (or vortexes), and other structures which cannot be seen in the brilliant light of the continuous spectrum, which alone is strong enough to register in the extremely short exposures required for obtaining a direct photograph.

A modification of the spectroheliograph, the spectrohelioscope, was invented by Hale for visual observation. Some phenomena, such as brilliant eruptions in hydrogen light (bombs), last only a few minutes and can best be detected and followed by means of prolonged visual observation.

5. Coronal Spectrograph.—In 1930 Bernard Lyot built on the Pic du Midi in France a coronagraph, an instrument with which he succeeded for the first time in photographing the corona when the sun was not in eclipse. The essential feature of its design is the elimination of scattered and diffracted light in the optical parts. The spectrum of the corona has since been observed regularly with various other coronagraphs.

III. CLASSIFICATION OF STELLAR SPECTRA

1. Methods.—The complex pattern of absorption features (and sometimes emission lines) presented in a stellar spectrum shows regularities which allow the stars to be arranged in sequences, which depend upon the physical and chemical conditions in their atmospheres. The principal groups, or divisions, in these sequences are the spectral types of the stars. These types can later be calibrated in terms of the physical variables (temperature, luminosity, etc.), if these variables can be measured independently for even a few of the stars. This whole procedure for rapid and direct assignment of physically significant types is known as spectral classification.

The first enduring system of classification resulted in the *Henry Draper Catalogue,* which gave spectral types of nearly 300,000 stars. The types: O, B, A, F, G, K, M, R, N, and S form a sequence according to effective temperature, which decreases from about 40,000° K for the earliest O-type stars to 2000° K or less for the latest stars of types M, N, or S. Since the calibration of types in terms of temperature is still subject to gradual improvement, the *Henry Draper Catalogue* types have remained useful as empirical indicators of temperature, particularly for the thousands of stars for which there are no later and more refined classifications.

It was noticed early by Miss A. Maury, and others, that stars having the same *Henry Draper Catalogue* type could differ in some features; and, after E. Hertzsprung and H. N. Russell showed that large differences in luminosity exist, W. S. Adams and A. Kohlschütter developed the spectroscopic criteria for classifying stars in two dimensions: luminosity and temperature. In a later system developed by W. W. Morgan, at the Yerkes Observatory, luminosity also is expressed by empirical units: the luminosity classes ranging from I for supergiants through II (bright giants), III (giants), IV (subgiants), to V for dwarfs and for main-sequence stars.

Stars of luminosity class I have absolute magnitudes of the order of -5, while the main sequence (class V) ranges in absolute magnitudes from -4 near type B down to the faintest M-type dwarfs at $+13$ or lower.

The hottest stars, class O, have spectra dominated by the lines of ionized helium; those of class B have hydrogen and neutral helium. In class A hydrogen is very strong, helium is weak or absent, and ionized metals, such as Fe II, Ti II, Mg II, are prominent. (The Roman numerals designate the state of ionization.) In types F, G, and K the lines of neutral metals, Fe I, Ti I, etc., become gradually stronger, and the lines of Ca II, Ca I, and Na I are conspicuous. Near type G we first observe bands of certain diatomic molecules, CH and CN, which also increase in strength as we pass toward the cooler stars. Types M, R, N, and S are characterized by very strong molecular bands of TiO in class M, C2 and CN in classes R and N, and ZrO in class S. Spectral types R and N have since been combined into a new class C with subdivisions which more accurately reflect temperature differences.

The luminosity criteria which are used within each spectral class differ greatly. In the hottest stars, classes O, B, and A, the hydrogen lines are much narrower in the more luminous stars (supergiants). In the intermediate and cool stars, lines of ionized

SPECTRUM OF THE SUN

Spectrum of the sun photographed at Mount Wilson Observatory at scale of 0.1 Å/mm. and a resolution of about 400,000. The horizontal streaks are due to bright granules and the darker interstices between them, and their relative motions give rise to Doppler shifts which cause the lines to have a jagged appearance

elements, such as Sr II in classes G and K, are enhanced in the more luminous stars. The molecular bands of CN, and others, can also be used as luminosity criteria.

Types M, S, and C overlap in their temperature ranges, and illustrate the importance of considering the chemical composition as a third factor determining the spectrum. The S and C stars appear to contain relatively more of such heavy metals as zirconium, lanthanum, and strontium as compared to type M. The ratio of carbon to oxygen is also greater in these two groups, and the excess of carbon as revealed in strong bands of C_2 is the defining characteristic of type C.

Less conspicuous but very important effects of composition appear in the yellow stars of types F, G, and K. The stars divide into several populations which differ in the ratio of hydrogen to all the heavier elements, and the more extreme cases of metal-poor stars form the population II of stars in globular clusters. The metal-poor stars tend to have weaker lines of metals in types F and G and abnormally weak bands of CN in the range G5 to K3. These subtle differences cannot usually be detected in objective-prism spectrograms.

An accurate classification of stellar spectra is important for three widely different problems: (1) the study of the physical properties of stellar atmospheres; (2) the statistical study of stars according to their principal characteristics; and (3) the study of the spatial arrangement of the stars in our galaxy by means of their luminosities.

It is important to have a clear understanding of the purpose of an investigation before the methods and the criteria are chosen. Thus, certain spectral features may be useful in empirical determinations of luminosities, but may be almost useless in studies of physical characteristics because they consist of unresolved lines or bands of different sources.

In addition to the *Henry Draper Catalogue,* which covers the entire sky and includes practically all stars brighter than apparent magnitude 8.2, there are supplements extending to much fainter magnitudes in limited areas. Other more specialized catalogues include the *Mount Wilson Catalogue of Spectroscopic Absolute Magnitudes*, and the catalogues of spectral types of the Hamburg, Berlin Babelsberg, Crimean, Warner and Swasey, Leander McCormick, Stockholm, Uppsala, Haute Provence, and other observatories.

An atlas of MK spectral types was issued by the Yerkes Observatory, and a catalogue listing all stars classified in this system has been completed by C. and M. Jaschek of La Plata. Other spectral atlases based upon spectrograms of various scales have been prepared at the Kitt Peak and Córdoba observatories.

Stellar classification, based upon spectrophotometric measurement rather than visual estimation of line strengths in the cooler stars, has been developed by B. Strömgren and others at the Copenhagen and Kitt Peak observatories. For types B, A, and F a corresponding three-dimensional classification was carried out at the University of Paris under the leadership of D. Barbier and D. Chalonge. All these studies owe much to the pioneer measurements of the CN bands begun as early as 1922 by B. Lindblad.

2. Interpretation of Spectral Classification.—The theoretical interpretation of the two-dimensional classification of stellar spectra rests upon the theory of thermal ionization proposed by M. N. Saha in 1920, and developed in later years by H. N. Russell, E. A. Milne, R. H. Fowler, and others. Some of the ideas underlying this theory were already present in the pioneering work of Norman Lockyer, but the exact mathematical formulation was first given by Saha.

In a gas exposed to high-temperature radiation, neutral atoms are constantly being ionized by quanta of light, and free electrons are being captured by ions. An equilibrium is set up by which the number of ionization processes is exactly balanced by an equal number of recombinations. The relative numbers of ions (n') and neutral atoms (n) depend upon the temperature of the radiation (T), the ionization potential of the atoms (I), and the partial pressure (p_e) of the free electrons, many of which may result from the ionization of some other element than the one we are considering:

$$\log \frac{n'}{n} = -I\,\frac{5040}{T} + \frac{5}{2}\log\, T - 0.48 - \log\, p_e$$

The observed intensity of a neutral line is directly dependent upon n, that of an ionized line upon n'. As the temperature increases, n decreases while n' increases, by virtue of the first factor containing T, which is more important than the second factor. The ionization is smaller when I is large. But the ratio n'/n also depends upon p_e and increases as the pressure decreases.

Consider two stars of the same temperature, but of different pressures, and suppose that we observe in their spectra lines of two elements having different ionization potentials. In the dense star the ionization is less than in the more tenuous star. Moreover, the element of higher potential will be less ionized than the one of lower potential. In practice we do not choose the stars according to temperature but according to spectral class. The latter rests upon a compromise of several slightly conflicting criteria, corresponding to different ionization potentials; for example, two stars classified as *F* do not have exactly the same temperature if their pressures are not alike; the more tenuous star has the lower temperature.

It must also be remembered that many elements can be ionized more than once, so that as T increases or p_e decreases, n' at first increases at the expense of n, reaching a maximum at definite pairs of values of T and p_e, after which it again decreases, while n'', representing the next stage of ionization, begins to increase. Ionization temperatures are determined for a sequence of stars, for which it may be assumed that p_e is constant, by observing at which spectral class lines of different ionization potential reach their greatest intensity. The condition for maximum intensity is obtained by differentiating the ionization formula with respect to T.

The theory of ionization suffices to explain many of the observed absolute magnitude effects in stellar spectra. For a given temperature high luminosity is equivalent to large size (giants) and therefore to small surface gravity and, in turn, small surface gravity indicates low pressure. The tendency of ionized lines to become stronger in giants is explained by the fundamental formula, but for a more complete interpretation it has been necessary to develop a very detailed theory of the formation of the continuous spectrum and of the absorption lines.

IV. RADIAL VELOCITIES

The Doppler principle gives the displacement of a spectral line ($\Delta\lambda$) as a function of the wavelength (λ) and the relative radial velocity of the source and the observer (v):

$$\Delta\lambda = \frac{\lambda \cdot v}{c}$$

where c is the velocity of light. The displacement can be measured on plates furnished with a comparison spectrum and, accordingly, v can be determined. The quantity thus obtained must be corrected for the components of the Earth's motion around the sun and the Earth's rotation around its axis. The precision of the determination depends upon the dispersion of the spectrogram, the precision of the laboratory wavelengths used for star and comparison lines, the sharpness of the star lines, the quality of the optical parts used, the uniformity of the illumination of the slit and the collimator by the star image, and other factors.

The probable error of a radial velocity measured on a single spectrogram can be made as low as 0.1 km/sec for a star with sharp lines (type G or K) taken with a dispersion of about 3 km/sec. For B- or A-type stars the probable error is about twice as great. Since the greater number of velocities have been measured on plates of much smaller scale, and there are systematic differences of the order of 1 or 2 km/sec between the results of different observatories, the velocities of most of the stars brighter than the seventh magnitude are known only to within about 2 km/sec.

The *General Catalogue of Stellar Radial Velocities* prepared by R. E. Wilson in 1953 contained 15,106 stars. Since then several

thousand more measurements have been made, and the task of keeping a continuously revised card catalogue of all known velocities has been taken over by the Commission on Radial Velocities of the International Astronomical Union.

Among the results obtained with the aid of radial velocities are the following: (1) the determination of the velocity (about 20 km/sec), and the direction in space, of the motion of the solar system with respect to the nearer stars; (2) the estimation of the random motions of the stars, which for the massive B stars averages as low as 15 km/sec, increasing down the main sequence to nearly 60 km/sec for typical M-dwarfs; (3) the recognition that the entire galaxy rotates around a distant centre located in the direction of the constellation Sagittarius, with a velocity of between 200 and 300 km/sec in the region where the sun is located; (4) the comparison of radial velocities and proper motions to determine mean distances of groups of stars of any one kind; (5) the discovery of a group of high-velocity stars which are moving with respect to the sun with speeds of the order of 100 km/sec, and in a direction opposite to the normal direction of galactic rotation; (6) the measurement of red shifts in very dense stars (white dwarfs), which are probably the gravitational red shifts predicted by Einstein (*see* GRAVITATION); (7) the law of linear increase with distance in the velocity of recession of external galaxies; (8) the discovery of numerous stars showing periodic variations in radial velocity—due to orbital motions of close double stars or to pulsations in the radii of individual stars (such as Cepheid variables); (9) the study of eruptions in novae and in other expanding shells of gas which surround such stars as P Cygni; (10) the discovery of stationary lines, which do not show the Doppler shifts characteristic of the stars but are interpreted as absorption produced by clouds of interstellar gas.

V. CONTINUOUS SPECTRA

The continuous spectra of the stars show conspicuous differences in the distribution of energy as a function of wavelength. These differences define the colours of the stars. The O and B stars are bluish, while the M, C, and S stars are red. Observations of the absolute energy distributions have been made at many observatories, originally by photographic photometry but now photoelectrically. These observations provide information about the surface temperatures of the stars, and the way in which interstellar matter has modified the colours that would be observed if space were completely transparent.

From the observations of nearby stars the colour temperatures are derived by adjusting T (temperature) in the Planck formula (*see* HEAT: *Radiation: Distribution of Energy in the Spectrum*) to give the best fit with the observed distribution. Differences in the energy distribution of two stars are often given in the form of "relative gradients":

$$\Delta\phi = \frac{c_2}{T_1} - \frac{c_2}{T_2}$$

where c_2 is the constant of the Planck formula. This procedure rests upon the observed fact that the energy distributions of many stars resemble black-body curves fairly closely. Accurate observations, however, have shown a number of important departures:

(1) In spectra of stars of types F, G, K, M, C, and S, which contain thousands of absorption lines, these lines not only reduce the energy radiated in many spectral regions but are often so crowded together that they overlap and leave no undisturbed continuum between them. The observed colours must be corrected for the effect of this "line blanketing." (2) At the limit of the Balmer series of hydrogen the spectra of moderately hot stars (class A) show a discontinuity, usually described as the "Balmer jump"; the continuous spectrum is abnormally weak on the violet side of λ 3647 Å. (3) In some stars the hydrogen lines appear in emission, and the Balmer jump is replaced by an abnormal strengthening of the spectrum shortward of λ 3647 Å. (4) The continuous radiation itself, of most stars, does not follow exactly a black-body curve. In a few unusual stars, such as P Cygni, the discrepancies are very large and give quite different colour temperatures in various regions of the spectrum. (5) Molecular bands in the cooler stars depress large portions of the spectrum. Thus, the energy distribution in the visual region of M-stars gives a measure not of colour temperature but merely of the changing band absorption. (6) The continuous spectrum of the sun is weaker and redder at the edge than in the centre, and the combined light is therefore a mixture of different energy distributions. This phenomenon of "limb darkening" must be present in most stars and has been detected in many eclipsing variables. (7) A strange inconsistency between the spectral class inferred from the absorption lines and observed colour temperature is noticed in several close double stars. This is attributed to the "reflection effect," which causes lines of relatively high excitation to be produced in the atmosphere of a cool binary component by the radiation of a hot component.

All of these phenomena are reasonably well understood. The theory of the continuous spectrum, and especially of the effect of limb darkening, is closely related to the problem of the physical mechanism which causes the gases in the outer layers of stars to be more or less opaque to continuous radiation. Continuous absorption at the series limits of H and He, and to a lesser extent of other elements, scattering of light by free electrons, and, in the cooler stars, continuous absorption from negative ions of hydrogen, and probably of other elements, are known to contribute to the continuous absorption coefficient (as distinct from the absorption coefficient within a spectral line).

VI. ABSORPTION LINES

By means of a spectrophotometer it is possible to measure the intensity of a star's radiation at successive wavelengths, from one edge of a spectral line to the other. When the results of these measurements are expressed in units of the intensity of the continuous spectrum, in the immediate neighbourhood of the line, and are plotted as ordinates against the wavelengths as abscissae, the resulting curve is designated as the profile (or contour) of the line. The profiles of faint lines are strongly affected by the finite resolving power of the spectrograph. For these it is customary to integrate the profiles and to express them in units of one angstrom of complete absorption. These values are designated as the equivalent widths of spectral lines. But for strong lines, like those of Ca II in the sun, the hydrogen lines in the A stars, etc., it is possible to derive physically significant profiles whose interest consists in the information they yield concerning the variation of the line-absorption coefficient with wavelength, and the character of the propagation of light through the atmospheres of the stars. Important information can be obtained from a curve in which the equivalent widths of the absorption lines are plotted as ordinates against the corresponding numbers of atoms effective in producing each line, as abscissae. Such curves are designated as curves of growth because they indicate the manner in which the intensity of a line grows as the numbers of atoms are increased.

1. Radiation Damping.—Many lines, like those of Ca II in the sun, have broad profiles with very deep, narrow pointed centres, where the residual light is only from 1% to 10% of the continuous spectrum, and with wings which extend very far to both sides (fig. 2). These profiles are well represented by an absorption coefficient which is inversely proportional to the square of the distance from the centre of the line. Physical theory suggests that this is the common form of the absorption coefficient of a single, undisturbed atom, where the gradual damping of the radiation in consequence of the loss of energy is the sole broadening influence. Since the mathematical form of this expression is known for a single atom of Ca II, it is possible from the observed profile to derive the number of absorbing atoms of Ca II per cm² in the atmosphere of the sun. This was first done by Unsöld, who used earlier measurements by K. Schwarzschild. In some spectral lines, for example those of Mg I in the sun or some lines of He I in B stars, the profiles are similar in shape to those given by radiation damping but their widths are much greater—just as though the constant of the formula were several times as great as that predicted by atomic theory. This phenomenon is explained by the effect of collisional damping, which was

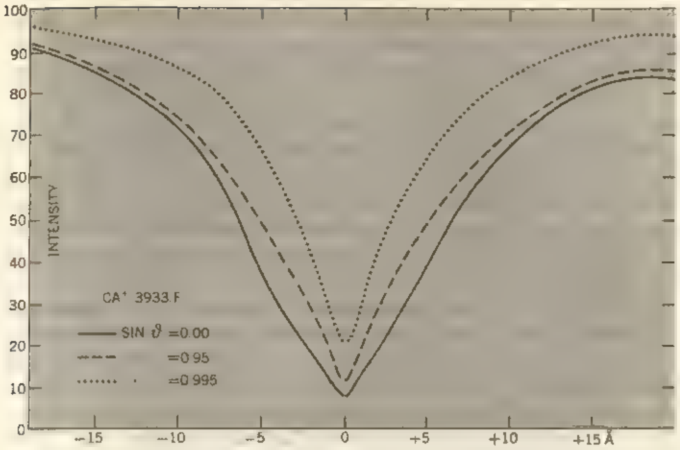

FIG. 2.—PROFILES OF THE STRONG LINE CA II K IN THE SPECTRUM OF THE SUN

Solid line: near the centre of the sun's disk; dashed line: at a point intermediate between centre and limb; dotted line: near the extreme edge of the sun. These profiles are broadened by the effects of radiation damping and collisional damping. The general weakening of the line from centre to limb is explained by the theory of transfer of radiation through a stellar atmosphere

first introduced into physical theory by H. Lorentz and later extended by Weisskopf and Wigner to include processes where atoms do not actually collide but experience close approaches to one another.

This form of broadening is important in dwarf stars of low luminosity and is unimportant in giants of high luminosity. In both types of broadening the equivalent width of a line increases as $\sqrt{N}$, where N is the number of absorbing atoms. For example, we know that the line K of Ca II is formed by twice as many atoms as the line H. In consequence the equivalent widths of the two lines in the sun are in ratio $\sqrt{2}$ to 1.

2. Thermal Doppler Effect.—In a stellar atmosphere the atoms are never quite undisturbed. They are moving about in all directions because of the high temperatures prevailing in these regions, and these motions are presumably in accordance with statistical theory.

Although every single atom radiates in accordance with radiation damping, some atoms are approaching while others are receding. The fraction which moves with a velocity v is, in accordance with Maxwell's law (*see* KINETIC THEORY OF MATTER), proportional to $e^{-(v/v_0)^2}$, where v_0 measures the average speed of the atoms. But if an atom moves with a velocity v in the line of sight it absorbs not in the normal position of the line but at a distance of $\Delta\lambda = \frac{\lambda \, . \, v}{c}$. If v_0 were very large, then radiation damping would be relatively unimportant. The profiles would be bell-shaped, in accordance with Maxwell's formula, and the equivalent widths would increase as N, and not as $\sqrt{N}$. For normal stellar temperatures radiation damping predominates for all but the very faintest lines. We therefore have a gradual transition in the relation between equivalent width and N: at first it varies as N, then as $\sqrt{N}$.

The corresponding bending of the curve of growth, as this relation is called, was observed in the sun by Minnaert, by Allen, and by others. (Fig. 3.)

3. Turbulence.—The curves of growth of many stars, such as α Persei or ϵ Aurigae, show a transition from the N to $\sqrt{N}$ relation at an equivalent width which is much too large to be explained by thermal motions. Moreover, these curves show a region of transition between the two major branches of the curve of growth, where the equivalent width changes little with N and remains almost horizontal. This phenomenon, first noticed by Struve and Elvey, is explained in terms of turbulent motions in the atmospheres of the stars. The sizes of the volumes of gas which are subject to these motions are not known, but they must be considerably smaller than the entire depth of the atmosphere, because otherwise the phenomenon would manifest itself differently in the curve of growth and would suggest convection, and not turbulence. The largest average turbulent velocity measured is about 67 km/sec, for the star 17 Leporis. The best analogue on the earth are the thermals which form on sunny days, but it must be remembered that the causes of the two phenomena are not the same.

4. Stark Effect.—In the presence of an electric field the spectral lines of many atoms are disturbed. In hydrogen the lines are split into several components; in helium some lines are little affected while some are displaced toward the red and others are displaced toward the violet, and completely new lines, never seen without electric fields, appear in the spectrum. It has never been possible to detect even the slightest evidence of a uniform electric field in the sun or stars. But the atmospheres of all stars contain vast numbers of charged particles, namely, free electrons and ions, each of which carries its electric charge and may in its thermal flight through the atmosphere come close enough to a radiating atom to produce an appreciable Stark effect (*q.v.*). We observe a combination of countless cases of this sort, with all possible distances between neighbouring particles and all orientations. The observed line should therefore have a blurred appearance, and its form can be predicted by a combination of statistical and physical theories.

The profiles which result from an application of the theory by Holtsmark differ greatly from those produced by damping or by Doppler effect. The wings are exceedingly broad and the centres of the lines are appreciably raised, so that the residual intensities may be as great as 50% of the continuous spectrum. Such profiles are observed in the hydrogen lines of dwarf stars, but, because of the symmetrical form of the Stark effect splitting in H, this was not sufficient to prove the existence of Stark effect in stars. The proof came when the lines of He I in B stars were found to show appreciable broadening in those lines which are sensitive to electric fields, and no broadening in those lines which are not sensitive to it. Stellar spectra also show several of the new lines forbidden by the quantum theory in the absence of fields; and the permitted lines show systematic shifts in accordance with the theory.

The Stark effect is appreciable in ordinary dwarfs and is very large in white dwarfs. It can be used to determine the luminosity of a star, because of the close relation between this quantity and the atmospheric density.

5. Rotation.—In many stars, especially of classes O, B, A, and F, all lines appear blurred, even those which are not sensitive to Stark effect, while at the same time the curve of growth shows no appreciable turbulence. The equivalent widths of the lines

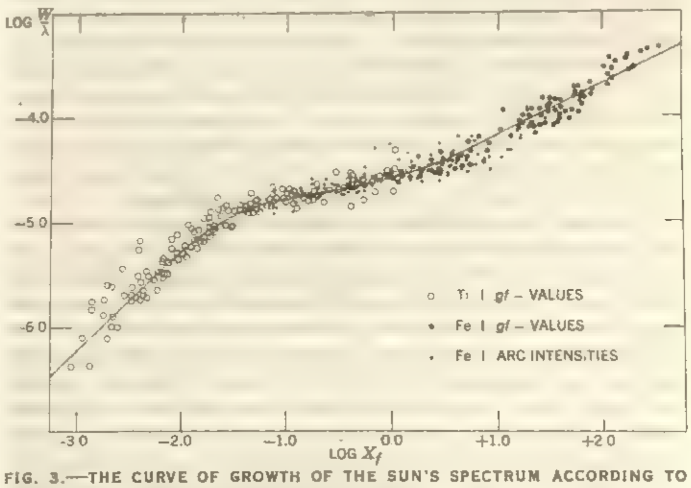

FIG. 3.—THE CURVE OF GROWTH OF THE SUN'S SPECTRUM ACCORDING TO K. O. WRIGHT

The abscissas are logarithms of the relative numbers of atoms (here designated as X_f) effective in producing the line and which can be inferred from multiplet and supermultiplet relations in spectroscopy, or from laboratory measurements. The ordinates are logarithms of the equivalent widths (W) of the lines divided by their wavelengths (λ). The curve is proportional to X_f in its lower left portion and is proportional to $X_f^{\frac{1}{2}}$ in its upper right portion. The bending over is the result of the thermal motions of the atoms in the sun's atmosphere

are not altered by this broadening influence, and the great widths are obtained at the expense of the central intensities. In some cases it has been shown that the widths of the lines are proportional to the wavelengths, if corrections are made to reduce them to the same equivalent width.

Since the Doppler effect is proportional to λ, and since no physical alteration of the absorption coefficient can fail to influence the curve of growth, or the equivalent widths of the lines, the conclusion is justified that we are dealing with some form of Doppler effect. Axial rotation, radial expansion, and convection suggest themselves. The effect of expansion is to produce an unsymmetrical profile which is deepest at the point of greatest negative displacement $\Delta\lambda_0$, and merges with the continuous spectrum at $\Delta\lambda = 0$. Since we can see only one hemisphere of an expanding star, the line does not extend into positive values of $\Delta\lambda$. Neither the asymmetry nor the preference for negative displacements agrees with the observations. We are left with rotation and convection.

To decide between them Struve and Shajn made numerous determinations of line profiles in close spectroscopic binaries. In these stars the components are almost in contact and it is reasonable to suppose that their rotational periods are equal to the period of orbital revolution. All have very broad and shallow lines, and this phenomenon is the more conspicuous the shorter the period. Since no such relation is expected in the case of convection, the "dish-shaped" line profiles can be attributed to axial rotation. In a few eclipsing binaries, for example in Algol, the line profiles become unsymmetrical during the partial phases of the eclipse and, as Rossiter and McLaughlin have shown, it is possible to derive from them the rotational velocity at the equator.

For single stars the line profiles furnish the values of $v \sin i$, where v is the equatorial velocity and i is the inclination of the star's axis of rotation to the line of sight. On the assumption of random orientation of the axes of rotation, mean values of the rotational velocity can be found for groups of stars. Following the early estimates of rotational velocities by Struve, Elvey, and Morgan at Yerkes, many more accurate velocities have been measured, and a catalogue by A. A. Boyarchuk and I. M. Kopylov of the Crimean Observatory (1964) listed $v \sin i$ for 2,558 stars.

The range of observed rotational speeds extends from 0 to more than 400 km/sec, with the longest values found in bright-line B stars. In ordinary absorption-line stars the mean $v \sin i$ reaches a maximum near B5 and declines steadily toward later types. A. E. Slettebak and others have shown that the giant stars of early type (B and A) rotate more slowly than dwarfs, while for types F and G the reverse holds and the giants are rotating faster. These results are consistent with current theories of the evolution of stars away from the main sequence. Among double stars the wide pairs rotate normally; as A. E. Slettebak expressed it, "Visual binary components apparently rotate as though each star were not aware that the other component is there." In contrast, close binary stars rotate very slowly and H. A. Abt has emphasized that there must be close interaction between the components, since their periods of rotation and of revolution are synchronized.

6. Stellar Line Profiles.—The formation of stellar absorption lines commonly involves the combination of two or more of the above mentioned widening agencies, and the resultant profile depends upon the manner in which the radiation is propagated through the star's atmosphere. It is necessary to take account of the fact that the atoms not only absorb but also reemit radiation, and that this emission occurs in all directions while the absorption takes place in radiation directed outward from the star. There are two extreme possibilities: the radiation may be reemitted without change of frequency but with change of direction only (pure scattering), or it may be redistributed in frequency according to the Kirchhoff-Planck function (pure absorption). The Balmer lines are believed to approach the case of pure absorption, while resonance lines involve a scattering process primarily.

The accurate calculation of line profiles for comparison with observations is now generally carried out by the method of model atmospheres. From preliminary "coarse analysis" by means of curves of growth a model structure giving the dependence of temperature, density, and continuous absorption on depth is adopted. Then the intensity at each point in the profile is computed by one of several possible methods of numerical integration of the equation for the transfer of radiation through the atmosphere. By using this technique of "fine analysis" of stellar atmospheres it has been possible to predict accurately the shapes of many lines in the spectra of stars of types B, A, and F. Extension to cooler stars has been hindered by incomplete knowledge of the sources of continuous opacity in their atmospheres, but rapid progress is being made.

7. Centre to Limb Differences.—The most powerful method for testing theories of line formation consists in the study of line profiles at different distances from the centre of the sun. It was shown originally by K. Schwarzschild that if a line is formed by pure absorption it should completely disappear at the limb of the sun. Actually, all strong solar lines become somewhat weaker at the limb, but they do not disappear (fig. 2). By combining these centre-limb differences in central intensities of lines with the limb darkening in continuous radiation, it has been possible to construct rather detailed models of the temperature distribution through the solar atmosphere.

8. Abundances of Elements.—Equivalent widths of atomic lines and depths of molecular bands are the data from which the chemical composition of stellar atmospheres is derived. Since the pioneer analysis of the solar spectrum by H. N. Russell in 1932, abundances in many stars have been estimated by means of curves of growth, and, in a few, by means of model-atmosphere calculations.

For the sun and most of the stars in its neighbourhood (stellar population I) abundances of the common elements are found. In their atmospheres the ratio of hydrogen to all other elements heavier than helium is about 5,000 to 1. There are, in addition, many stars whose spectra give evidence of quite different chemical composition. Of particular interest are the metal-poor stars (stellar population II) in which the content of heavy elements is reduced by additional factors of from 5 to 100 as compared with hydrogen. In the spectra of F- and early G-type stars, where the lines of common metals such as iron are just becoming conspicuous, this deficiency in abundance not surprisingly reveals itself by a weakening of the metal lines as compared to the Balmer lines of hydrogen. At lower temperatures, however, these metal lines are normally strong enough to lie on the flat part of the curve of growth, where even a considerable change in numbers of atoms will have little effect on the appearance of the lines. In these types the features, which are most responsive to the increased opacity corresponding to an excess of hydrogen (since continuous absorption in their atmospheres is proportional to the amount of H^- present), are molecular bands in which the absorption is spread over an appreciable range in wavelengths. Thus, the blue and violet bands of CN are weakened in metal-poor giants of types G5 to K2, while molecules containing hydrogen, such as CH, show their usual band strengths. The most extreme examples are found among the stars populating the nearby spherical halo surrounding the galactic disk—the members of globular clusters and isolated stars with very large velocities in space. It appears probable that such stars were formed in parts of space where the original hydrogen gas was not greatly contaminated by heavier elements, synthesized in the interiors of stars of earlier generations.

In contrast to the metal-poor stars are those in which the ratio of all the heavier elements to hydrogen is considerably greater than in the sun. Thus there are some strong-line G- and K-type stars in which there appears to be a moderate enrichment of nearly all the metals. More extreme differences are shown by barium stars, carbon stars, and S-type stars. In such objects the lines and bands due to heavy elements (Zr, Sr, La, etc.) are enhanced in relation to the metals of the iron peak (Fe, Ti, etc.). In the carbon stars there is also a great excess of carbon over oxygen, and there appears to be some increase in the proportion of carbon to oxygen in type S also. It appears that these heavy-metal stars are relatively young objects formed from the debris of earlier stars in which the heavy elements were formed in the interiors before

being blown out into space, but it is also likely that inside the S- and C-stars, which are giants, the burning of helium and carbon is probably going on at the present time. *See* STAR: *Formation of the Elements in Stars.*

VII. SPECTRA OF STARS OF UNUSUAL INTEREST

In addition to the main groups of stars, there are many individual stars and groups which possess spectral peculiarities that reveal significant astrophysical information.

1. The Wolf-Rayet Stars.—Numbering fewer than 100 out of about 500,000 well-observed stars, these show continuous spectra upon which are superposed broad emission bands of atoms of a high degree of ionization, such as He II, C III, C IV, N III, N IV, N V, etc. These bands are often flanked on their violet sides by more or less diffuse absorption lines—a phenomenon which is believed to indicate that the lines and bands originate in shells expanding in all directions with velocities of several hundreds or even several thousands of km/sec. No forbidden lines have been found among the various features, which suggests that the shells cannot be very great in extent. A large fraction of the known Wolf-Rayet stars are close binaries, and in some the spectra of the companions turn out to be normal stars of class O or B. In these cases the Wolf-Rayet stars have much smaller masses.

C. S. Beals, at Victoria, discovered that there are two kinds of Wolf-Rayet stars, one group in which carbon lines are strong and another in which nitrogen predominates. Both groups have been arranged in sequences of decreasing ionization by Beals, and by W. A. Hiltner, but there are many peculiarities which need further explanation.

2. Stars with Bright Lines.—Some stars that are otherwise normal in spectrum have bright lines of hydrogen, and of other elements, in addition to the usual absorption lines. Sometimes these lines are broad, or even double; in other stars they are sharp and narrow. The broadening appears to be caused by Doppler effect, but the nature of the motions involved is not the same in all cases. In a large group of bright-line stars of classes B and A the motions are rotational in character, a tenuous shell or ring of gas revolving around a normal star which itself has such a rapid axial rotation that it approaches (or perhaps even reaches) the condition of rotational instability. Several stars of this kind happen to be members of close eclipsing double stars. The occulting star in its path eclipses first the approaching lobe of the rotating shell, then the star itself, and, finally, the receding lobe of the shell. In other stars the motions are those of expansion, as in Wolf-Rayet stars and in novae, and in still others they are of an irregular or turbulent character. In many stars the bright lines vary in the course of years.

A separate group is formed of various stars of the cooler classes which also show bright lines of H, Ca II, Fe I, Mg I, Si I, etc. Even the sun has weak central emissions in the lines designated as H and K of Ca II, and in other stars, like Arcturus, they are fairly strong. The origin of these emission lines is somewhat obscure. O. C. Wilson has shown that the widths of the Ca II emission lines are strongly correlated with the luminosities of the stars. F. Hoyle and Wilson have suggested that the turbulent motions which give rise to the line broadening is produced in the convective layer just below the photosphere.

Stronger emission lines are found in the spectra of Mira variable stars, but only at certain phases of their light curves. Just before maximum light the Balmer lines become conspicuous in emission. After this maximum they gradually weaken and disappear before minimum, while many metallic emissions, particularly Fe λ 4308 Å, Mg λ 4571 Å, and In λ 4511 Å reach their greatest strength on the descending branches of the light curves. This remarkable systematic behaviour has not been fully explained, although P. W. Merrill and A. D. Thackeray noticed that the unusual strength of Fe λ 4202 Å, and Fe λ 4308 Å, and In λ 4511 Å, involves fluorescence due to coincidence of their lower levels with the upper levels of strong ultraviolet lines of hydrogen and iron. Another significant fact, observed by Merrill and A. H. Joy, is that the Balmer emission lines are weakened by absorption of Ca II ions and TiO molecules, which must lie at greater heights than those

(BOTTOM RIGHT) A DIRECT PHOTOGRAPH OF THE CLUSTER OF THE PLEIADES CONTAINING HUNDREDS OF STARS ENMESHED IN A DIFFUSE NEBULOSITY

at which the emission lines are formed.

An interesting but small group of stars have spectra containing forbidden emission lines, *i.e.*, lines which are not produced in the laboratory because the corresponding transitions are not permitted by the rules of the quantum theory. Some of these stars have weak continuous spectra upon whose background are seen numerous bright lines of H, Fe II, [Fe II], Fe III, [Fe III], [Fe V], [Fe VI], [Fe VII], and probably even [Fe X] and other elements. The bracketed designations of elements stand for forbidden lines. Since the ionization potentials of these substances differ widely, by Saha's formula of ionization they could not all be observed in a gas of uniform temperature and pressure. The conclusion is that they come from different regions of a highly complex nebulous structure. P. W. Merrill found that most of these stars also show absorption bands of TiO. It is believed that they consist of three sources: a cool star, a hot companion, and a gaseous mass in which the radiation of the hot star causes ionization and excitation.

In some cases, like the star Antares, the binary can be observed directly. Its bright component is a cool giant, but it also has a faint, hot companion whose spectrum reveals forbidden [Fe II]. Swings and Struve found that in these stars the forbidden lines of [Fe II] and those permitted lines of Fe II, whose energy levels are low, are abnormally strong, so strong, in fact, that an impossibly low excitation temperature results when the intensities are interpreted by means of the Boltzmann exponential relation. The conclusion is that the mechanism of excitation consists in collisions between atoms and electrons, and not in the process of line absorption or ionization, and that the emission lines are produced in a small nebulosity, about 3 sec. of arc in diameter, which surrounds the hot star.

3. T Tauri Variables.—The spectra of these stars also show emission lines superposed upon fairly normal G or K type absorption spectra. According to A. H. Joy and G. Herbig, they are always found in or near large cosmic dust clouds. Herbig suggests that they are very young stars, of small mass, which are

still contracting and have not yet reached the main sequence. Their absorption lines are broadened by rapid axial rotation, as would be expected in young stars which have not experienced the braking action of magnetic fields or which have not had time to transfer their angular momenta to a system of planets. The spectra and brightness of the T Tauri variables undergo irregular variations.

4. Spectra of Shells.—In 1938 the spectrum of the star Pleione, one of the brighter members of the cluster of the Pleiades, underwent a sudden change. For about 30 years the spectrum had been that of a normal B star with very diffuse absorption lines of H and He. It now developed emission lines of H and a set of sharp absorption lines of H, Fe II, Ti II, Ca II, and other ionized elements. In the course of several years these sharp lines became very strong and indicated a tendency toward lowered ionization. A number of other stars which possess similar spectra are known, though they have not often been observed in the process of formation. The source of these spectra is designated as shells because it is inferred from the reduced intensities of a few characteristic lines that the gases, in which they are formed, are not at the surface of the star but are removed above it to several times its radius. The phenomenon producing these lowered intensities is designated as "dilution of radiation." To obtain normal intensities the populations of the different atomic levels must correspond to Boltzmann's relation. If the mechanism of excitation is the absorption of radiation this happens only when the radiation corresponds to conditions of thermodynamic equilibrium. When a gas is illuminated by a distant star, the radiation is "diluted" and those excited energy levels, which possess transitions to lower terms, are depopulated in the same ratio that the apparent area of the star as seen from the gas bears to the complete sphere. The phenomenon of dilution causes the lines of Mg II 4481 and Si II 4128, 4131 to appear abnormally weak. It also produces remarkable changes in the relative intensities of the He I lines. The formation of shells seems to be related to the process of axial rotation of the stars. In some shells (ζ Tauri and ϕ Persei) the shell is stratified and different layers of it revolve at different speeds around the main body.

5. Pulsating Stars.—Among the stars whose radial velocities undergo periodic changes are the variables of the Cepheid and the long-period groups. The former have velocity curves which may be described as the mirror images of their respective light curves. The variations in velocity are not caused by orbital motion, as in ordinary binaries, but are believed to be produced by periodic pulsations. The periods vary from a small fraction of a day to about 50 days. In some short-period variables two, three, or even more periods combine to produce beat effects in the radial velocity curves and the light curves. Some of these periods represent the higher modes of the fundamental period. The spectral classes also undergo periodic variations, being hottest near maximum light, or near minimum radial velocity. There is conflicting evidence from the luminosity criteria, but the hydrogen lines give maximum luminosity near maximum light; this correspondence is not physically obvious because the observed change in brightness (of the order of one stellar magnitude) is fully accounted for by the variation in temperature, and the elementary pulsation theory would predict maximum radius and, hence, minimum atmospheric pressure halfway from minimum toward maximum radial velocity. Evidently the hydrogen atmosphere is expanded at the time of maximum light, and the phenomenon is only indirectly related to the pulsation.

The Mira variables also are probably pulsating stars. Merrill and Joy showed that there is a relationship between their period and average spectral class, later spectral classes being generally associated with longer periods until type M7e is reached at periods of about 400 days. For the few stars of even longer period the type may be either early or late Me, which suggests that these long periods may not be the fundamental ones in some stars. There are also Mira variables of types Se or Ce.

Among the hotter stars there is a special group of pulsating variables, the β Canis Majoris stars, which have been studied most thoroughly by O. Struve. They have spectral types in the range B1 to B3, periods generally less than a quarter of a day, and very small amplitudes of variation. Their pulsations appear to be similar to those of Cepheids. At somewhat later types (F) there is another group of stars, the δ Scuti variables, which also have very short periods and small amplitudes.

6. Magnetic and Spectrum Variables.—In the *Henry Draper Catalogue* Miss Cannon noted that in the spectra of a few percent of the A-type stars the metallic lines are stronger than in normal stars. Those in which there is some enhancement of all the usual metals were defined as metallic-line (Am) stars by W. W. Morgan. More anomalous, however, are those in which the lines of certain ions only, such as Sr II, Eu II, Mn II, etc., stand out inconsistently. These are the peculiar A-stars (Ap). A. J. Deutsch pointed out that the hottest stars in the group tend to show enhancement of Mn II; as the temperature decreases down the sequence the stars tend to show, in turn, abnormally strong lines of Si II, Eu II, Cr II, and Sr II. The intensities of these lines in some Ap stars vary periodically, and in a few cases quite small variations in light occur also. The radial velocities tend to vary with the same periods as the line intensities.

The Ap stars that are spectrum variables have been found by H. W. Babcock to have large and variable magnetic fields. These fields may have strengths of several thousand gauss, and the changes in field strength are frequently great enough to reverse the polarity as determined from the Zeeman patterns of the spectral lines. Thus, the field of α^2 CVn changes from -1400 to $+1600$ gauss in a period of 5.7 days, with the Eu II lines strongest at -1400 gauss, and the Cr II lines at maximum when the field is positive. These great variations seem to rule out deep-seated abundance anomalies as the cause of the spectral peculiarities. The period of variation is apparently the period of axial rotation of the star, and it is generally agreed that some magneto-hydrodynamic process coupled to axial rotation must be involved. None of the detailed theories, however, has yet accounted for all the observations of the Ap stars.

Magnetic fields, extending up to several hundred gauss in strength, have been observed by Babcock in a few stars of later type also, including S-type stars, and in the cluster-type variable RR Lyrae.

7. Red Giants with Outflow of Matter.—As early as 1935 it was pointed out by W. S. Adams that on the Mount Wilson coudé spectrograms of α Orionis, and other cool stars, the strong absorption lines arising from the lowest atomic terms were double. The redward components were the normal, rather wide, lines of the reversing layer, but the sharp violet-displaced components were interpreted as being caused by upward-moving currents of gas. Later studies by A. J. Deutsch showed that these currents were expanding envelopes extending to several times the radii of the stars and moving at speeds of from 2 to 25 km/sec. This outflow of matter represents a considerable loss of mass, estimated by Deutsch to be at least 3×10^{-8} solar masses per year in the case of α Herculis. Similar circumstellar lines, but with smaller displacements, are found generally in ordinary giants of type later than MO.

This outflow is not surprising, since it had been pointed out earlier (G. A. Shajn) that the effective gravity may be nearly zero at the surfaces of cool luminous stars, so that only slight outward forces would be needed to allow atoms to exceed the velocity of escape. There are also arguments from evolutionary theory, and from the distribution of the several kinds of stars in clusters, that loss of mass should occur during some part of a star's lifetime.

Of course, loss of mass is involved in eruptive events such as novae, but the spectroscopic evidence now shows that gradual outflow of matter is also important, at least during the cool giant phase of evolution. That either sporadic or continual ejection of gases can occur in hot stars also is shown by spectroscopic observations of expanding shells in P Cygni stars and very luminous supergiants such as ρ Cassiopeiae.

8. White Dwarfs.—Since white dwarf stars have luminosities about 8 to 10 magnitudes below the main sequence, densities of

10,000 or more, and degenerate cores consisting largely of helium, with practically all their hydrogen confined in relatively thin surface layers, it might be expected that their spectra would be unusual. Actually they display a great variety of spectra, which have been divided by J. L. Greenstein into nine main types, each prefixed by the letter "D." Type DC has an almost continuous spectrum, but a wide range of colours. Others contain the usual Balmer lines, often greatly broadened by pressure effects. In the hotter stars helium lines are observed, with or without the hydrogen lines. In DF and DG spectra the H and K lines of Ca II dominate the spectrum. A few can be described as white-dwarf carbon stars, since they show two heads of the C_2 molecule near λ 4670 Å.

Perhaps the most puzzling is the spectrum of the star AC +70°8247, found by R. Minkowski to contain unidentified absorption bands near λ 4135 Å. For only a few of such white dwarfs has it been possible to construct model atmospheres that predict successfully their spectral characteristics.

9. Infrared Stars.—Until recently the coolest known stars were several Mira variables for which temperatures near 1600° K at minimum light had been measured radiometrically by E. Pettit and S. B. Nicholson as early as 1933. The marked improvement in the efficiency of cooled photoconducting cells as detectors of infrared radiation made it possible for the California Institute of Technology to organize in 1963 a systematic survey of the sky in two infrared ranges, 0.68–0.92 μ and 2.01–2.41 μ. Stars of known colour made up about 99% of those recorded, but the remaining 1% were so much redder that they are well described as infrared stars. Among them the only ones bright enough to appear even on the red plates of the Palomar Sky Survey were identified with very faint stars, below the 16th magnitude. Of these only the brightest, NML Cyg, could be seen visually with the 200-in. reflector.

In general, the spectra of infrared stars in this region resemble those of carbon stars more closely than S- or M-type spectra, particularly in the deficiency of water vapour.

The Taurus infrared star has been shown to be a Mira variable, but the Cygnus object does not show large variations in light. The temperatures of these remarkable stars appear to be about 1000° K or even less.

VIII. QUASI-STELLAR RADIO SOURCES

Many radio sources have been identified with galaxies that can readily be observed optically. There were a few sources of very small angular diameter, however, that were found about 1960 to coincide with objects that appeared essentially stellar on direct photographs. These objects have dissimilar spectra with emission features for which no identification was found for several years. The clue to the problem was found by M. Schmidt in 1963 when he noted that some of the broad lines in the spectrum of the radio source 3C273 corresponded to Balmer lines of hydrogen shifted to the red by 16% of their wavelength, or 600 to 700 Å. The lines in other sources which lacked the Balmer lines were then identified by Schmidt, Greenstein, and T. A. Mathews with ultraviolet lines of other elements, including ionized magnesium and forbidden lines of ionized oxygen, etc., by assuming similar or even greater red shifts for those objects. Red shift is usually measured as the change in position of a line divided by its original wavelength, or $z = \Delta\lambda/_{\lambda}$. The largest values of z measured for any quasi-stellar sources are very nearly 2.0. With this shift the line of C IV normally observed in the vacuum ultraviolet at λ 1549 Å is actually found in the blue-green at about λ 4647 Å.

The quasi-stellar radio sources (or quasars) thus have greater red shifts than even the faintest and most distant of the ordinary galaxies that can be observed. This implies that the quasars are extremely distant and luminous objects, if their red shifts are considered as cosmological; *i.e.*, Doppler shifts obeying the same relation between shift and distance as those of other galaxies. One objection to this interpretation is that the light of several of the sources has been found to vary appreciably in intensity over intervals of even a few weeks, and it is difficult to account for such short-period variations in an object of galactic dimensions. If, on the other hand, they are objects lying within our own galaxy, another explanation must be found for the enormous red shifts. It seems certain, at least, that the quasi-stellar sources cannot be very dense dwarf stars close to the solar system, for those which are bright enough to have been found on old photographs show no significant angular motions in the sky.

See SUN; PLANETS; COMET; NEBULA; *see* also references under "Spectroscopy, Astronomical" in the Index.

BIBLIOGRAPHY.—One of the most comprehensive modern reference works is the series *Stars and Stellar Systems* (1966), under the general editorship of G. P. Kuiper. The topics discussed in the volumes of that series are as follows: Spectrographs—vol. 2, ch. 2 (I. S. Bowen), Spectral classification—vol. 3, ch. 8 (P. C. Keenan), Continuous spectra—vol. 6, ch. 8 (A. D. Code), Rotation and turbulence—vol. 6, ch. 8 (S. S. Huang and O. Struve), White dwarfs—vol. 6, ch. 19 (J. L. Greenstein). A more detailed account of spectral classification will be found in W. W. Morgan *et al.*, *An Atlas of Stellar Spectra* (1943). Magnetic Variables and Ap Stars are discussed in the chapter, "Magnetic Stars," by P. Ledoux and P. Renson in *Annual Review of Astronomy and Astrophysics*, vol. 4 (1966). Special types of stars brighter than magnitude 6.5 are given in *A Catalogue of Bright Stars*, edited by D. Hoffleit. The *Henry Draper Catalogue* was issued as *Harvard Observa-*

tory Annals, vol. 91–99 (1918–24). The theory of continuous spectra and absorption lines is covered by L. H. Aller, *Astrophysics*, vol. 1, *The Atmospheres of the Sun and Stars*, 2nd ed. (1963).

(O. St.; P. C. Ke.)

SPECTROSCOPY, X-RAY. A beam of short-wave electromagnetic radiation called X rays is scattered when it strikes a crystal, much in the same way a beam of light is diffracted by a ruled grating. The science that deals with the study of X-ray diffraction is X-ray spectroscopy. Its practical applications (including the chemical analysis of metal alloys, liquid solutions, and gases) are discussed in the concluding section of X Rays.

History.—Max von Laue discovered in 1912 that radiations in the X-ray wavelength range of 10 to 0.1 Å are diffracted by natural crystals whose layers of atoms are only a few angstrom units apart ($1 \text{ Å} = 10^{-8}$ cm.). Ruled gratings that work well in registering ordinary optical spectra with wavelengths down to about 2000 Å are of no value in diffracting X rays. To register the region between 2000 and 10 Å, other methods were subsequently developed.

In one of his first papers concerning X rays, W. C. Röntgen noted that X rays produced in an ordinary X-ray tube differ in quality when the vacuum of the tube and particularly the voltage on the tube are varied. It was shown early that the X radiations became more penetrating as the voltage on the tube was raised. The degree of penetration (usually measured in terms of the thickness of aluminum necessary to reduce their intensity by half) was used as a means of characterizing the quality of the radiation.

It was by this means also that C. G. Barkla was able to show that the different elements when excited so as to give off X rays all have their own characteristic radiations. For instance, for an element such as silver Barkla showed the existence of two characteristic radiations called the K and L radiation having very different penetrating powers.

These two characteristic radiations, the K series and the L series, were experimentally verified for a great number of elements. The measurements of their penetration in aluminum showed that their hardness (ability to penetrate) increases regularly for both series as the atomic weight of the emitting element increases.

Basis of X-ray Spectroscopy.—The diffraction patterns which W. Friedrich and P. Knipping obtained by allowing a fine beam of X rays to pass through a crystal as suggested by Laue induced W. H. and W. L. Bragg to perform the experiments which were the first step in the development of X-ray spectroscopy. As the Braggs showed, a monochromatic X-ray beam is reflected by a cleavage face (or any other atomic planes) of a crystal according to the ordinary laws of optical reflection; *i.e.*, the incident and the reflected beams are in the same plane, perpendicular to the reflecting face; further, the angles between these two beams and the reflecting face are equal. In addition to these laws the following condition must be fulfilled if reflection is to occur

$$n\lambda = 2d \sin \psi_n \tag{1}$$

where λ is the wavelength of the monochromatic radiation, d is the distance between two adjacent atomic layers parallel to the reflecting plane, ψ_n is the angle between the beam and the plane, and n indicates the order of the reflection (fig. 1).

This equation, generally known as Bragg's law, forms the basis for measuring the wavelengths of X rays. This law needs a small correction, due to the fact that the wavelength is slightly different in a vacuum (or air) than in a crystal.

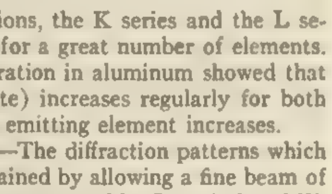

FIG. 1.—REFLECTION OF X RAYS ACCORDING TO BRAGG'S LAW (*see* TEXT)

Spectrometric Methods.—The wavelength region of ordinary X rays extends over the range 0.1 to 10 Å. The rays show different penetrating properties, and are termed hard (penetrating) or soft X rays. The region of hard X rays extends from 0.1 Å to about 1.5 Å, the wavelength where the absorption in air becomes important. In the soft X-ray region the great absorption in air makes it necessary to enclose the spectrometer in a vacuum container. The X-ray region from 10 Å and up to ultraviolet is called the ultrasoft region. Ultrasoft X rays can be studied by using ruled gratings.

FIG. 2.—REFLECTION OF X RAYS BY CRYSTALLOGRAPHIC PLANES: (A) REFLECTION MOUNTING FOR SOFT X RAYS, (B) MOUNTING FOR HARD X RAYS

In most spectrographs the X-ray beam incident on the crystal will be reflected by the crystallographic planes that are parallel to the crystal surface. This so-called reflection mounting of the crystal is best suited for the soft X-ray region (fig. 2A). In the hard X-ray region the angle ψ is small and the X-ray beam therefore sweeps almost parallel to the crystal. In this case the transmission mounting is the most suitable (fig. 2B). The short wavelength radiation can easily penetrate the crystal plate and the reflection occurs at crystal planes that are perpendicular to the crystal surface.

The first X-ray spectrographs used a plane crystal as is shown diagramatically in fig. 3. The different monochromatic rays which constitute the beam coming from the X-ray source and defined by a slit are reflected by the crystal at different angles according to Bragg's law (equation [1]). If the angles may vary from ψ_1 to ψ_2 only such rays are reflected whose wavelengths have values between λ_1 and λ_2 where

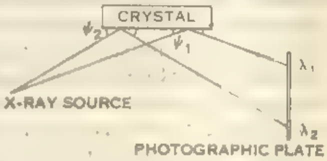

FIG. 3.—PRINCIPLE OF EARLY X-RAY SPECTROGRAPH USING PLANE CRYSTAL

$$n\lambda_1 = 2d \sin \psi_1$$
$$n\lambda_2 = 2d \sin \psi_2$$

The photographic plate therefore registers a spectrum ranging from λ_1 to λ_2. The region of wavelengths can be varied by turning the crystal. The wavelength of any spectral line on the photographic plate can be computed by equation (1) from its position on the plate.

FIG. 4.—PRINCIPLE OF THE TWO-CRYSTAL SPECTROMETER: (A) CRYSTAL AT PARALLEL POSITION, (B) CRYSTAL AT ANTIPARALLEL POSITION

The resolving power (and the sharpness of the lines) of a crystal spectrometer depends on the slit width and the distance between slit and crystal. In the two-crystal or double-crystal spectrometer the slit is replaced by another crystal (fig. 4). The first crystal selects a wavelength region which is analyzed by the second crystal. This crystal can be put in two different positions. At the parallel position the outgoing beam is parallel to the incoming beam throughout the wavelength region (fig. 4A). If the second crystal is turned to the antiparallel position the beam is deflected twice (fig. 4B). The crystal has thereby been turned through an angle of $180° - 2\psi$. The wavelength is then computed by equation (1). Each setting of the second crystal allows only a very narrow wavelength band to be reflected. The width of this wavelength band depends on the quality of the crystals and is usually narrower than the width of a spectral line. In using the instrument the crystal is gradually turned through the wavelength region to be investigated; the reflected intensity is measured in each setting of the crystal by means of some counting device; *e.g.*, a Geiger-Müller counter. Photographic registration is never used at this instrument.

The spectrometers mentioned above, especially the double-crystal spectrometer, have the disadvantage of low luminosity. A great improvement of luminosity was achieved by the principle of bent-crystal spectrometers, first formulated by J. W. M. DuMond and P. Kirkpatrick in 1930. A reflecting type of spectrograph with bent crystal was first constructed by H. H. Johann in 1931. A thin crystal plate, C in fig. 5A, is bent cylindrically to a radius r and a circle is drawn with r taken as its diameter. This circle, which corresponds to the Rowland circle in optical spectroscopy, causes rays coming from a point A on the circle to be reflected and focused on another point B on the circle. Because the centre of curvature of the crystal O also lies on the Rowland circle,

Bragg's law is met for the reflection. The focusing is not absolutely perfect, however, since the crystal does not follow the Rowland circle smoothly. The focusing defects are not severe if the crystal aperture α is small and the Bragg angles great (long wavelengths).

A transmission type of bent-crystal spectrograph was first built by Y. Cauchois in 1932. Rays from the focal spot directed toward a virtual object point A are focused at B (fig. 5B). The rays are reflected by the internal crystal planes and consequently this spectrometer is best suited for short wavelengths. As in the Johann spectrometer the radiation is detected by a photographic plate or by means of a counter with a slit.

Detectors for X rays.—In spite of its poor sensitivity, especially for hard radiation, the photographic plate is the most important X-ray detector and the only one which simultaneously registers all lines in the spectrum (*see* NUCLEAR INSTRUMENTS).

Modern precision spectrometers are often equipped with counting detectors, however, where the single quanta produce voltage pulses, counted and registered by electronic devices. Geiger-Müller counters or proportional counters are used for soft X rays and scintillation counters preferably for hard X rays. The proportional counter and the scintillation counter require more elaborate electronic devices than the Geiger-Müller counter but they offer the great advantage of giving output pulses that are proportional in voltage height to the energy of the radiation. By electronic circuits it is possible to discard pulses of wrong height

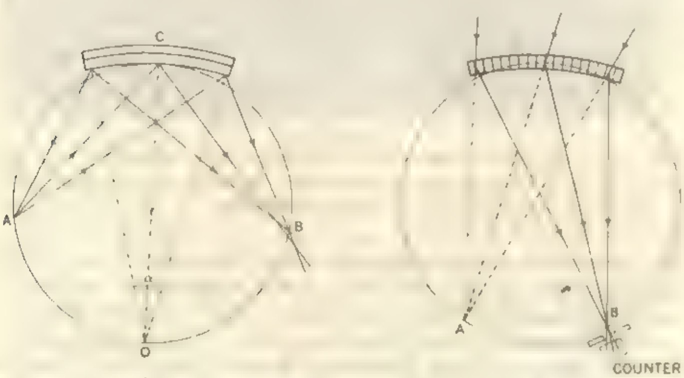

FIG. 5.—PRINCIPLE OF BENT-CRYSTAL SPECTROGRAPHS AS USED IN (A) A REFLECTING SPECTROGRAPH AND (B) A TRANSMISSION SPECTROGRAPH

arising from stray radiation, thus diminishing the background disturbances. Fig. 6 shows an X-ray spectrum detected by a curved-crystal spectrometer with a scintillation counter.

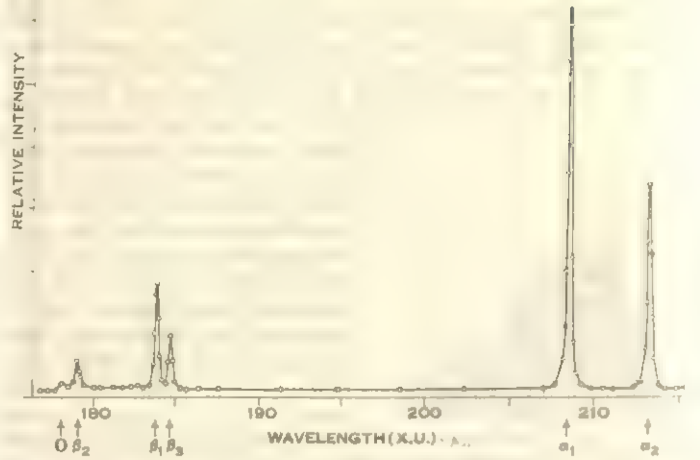

FIG. 6.—K-SPECTRUM OF TUNGSTEN REGISTERED BY A CURVED-CRYSTAL SPECTROMETER

Exciting X-ray Spectra.—To excite the X-ray spectrum of a substance, a small piece of it is placed as target material on the anticathode of an X-ray tube. After the tube has been exhausted to a suitable vacuum, a high potential (10 to 150 kv.) is applied to the electrodes of the tube, causing the anticathode to be bombarded by electrons from the cathode. The kinetic energy of the electrons imparted to the bombarded atoms is partially transformed into heat and light, and partially to X rays.

There are two main ways of producing a bombardment team of electrons with the X-ray tube. In the first method, the tube has a vacuum of 0.01 to 0.001 mm. Hg. The high voltage causes the gas remaining in the tube to ionize, with the positive ions being thrown against the aluminum cathode. The collision between the positive ions and the cathode sets free a number of electrons. The electrons travel in the opposite direction—from the cathode to the anticathode—and bombardment of the anticathode gives rise to X rays characteristic of the substance of the anticathode.

In the second method, the vacuum of the tube is much lower and there is no gas ionization of any importance. The bombarding electrons are supplied by the heated filament (usually of tungsten) in the cathode. This is the most commonly used type of X-ray tube because the electron beam can readily be controlled by adjusting the heating current in the cathode.

When analyzing materials, it is often necessary to change the substance on the anticathode; hence the tube must be built so the anticathode can be detached easily. This can be done by mounting the anticathode in a special joint. A tube which permits rapid change of both cathode and anticathode is shown in fig. 7. The tube is built of metal with water cooling to permit a high output of energy. A small window of aluminum or other low-absorbing material permits the study of radiation of longer wavelengths, which would be absorbed by the glass walls of an ordinary tube.

Another way of exciting X-ray spectra is to irradiate the substance with an intense beam of X rays. In this case the substance emits secondary rays which, with a few exceptions, are identical with the X radiation sent out by the substance when used as an anticathode in an X-ray tube. This method does not, however, give the same intensity as the former.

X-ray Wavelength Units.—In early X-ray work the wavelengths were given in angstrom (Å) units. Since this unit is too big for convenience, the X unit (X.U.; 10^{-11} cm.) was introduced.

The X-ray wavelengths are determined by crystal spectrometers and this requires an exact knowledge of the grating constant d of the crystal (*see* equation [1]). As experimental technique improved, the spectrometric measurements of X-ray lines became definitely more accurate than the measurements of the grating constants, which had to be determined from measurements of density and dimensions of cubic crystals. For these reasons the X unit has been defined by the lattice constant of the common plane in calcite set equal to 3,029.04 X.U. at 18° C. Later, E. Bäcklin, F. Tyrén, and other investigators succeeded in measuring some soft X-ray lines using ruled gratings. A direct connection between the angstrom and X units was thus established and by agreement 1,000 X.U. = 1.00202 Å.

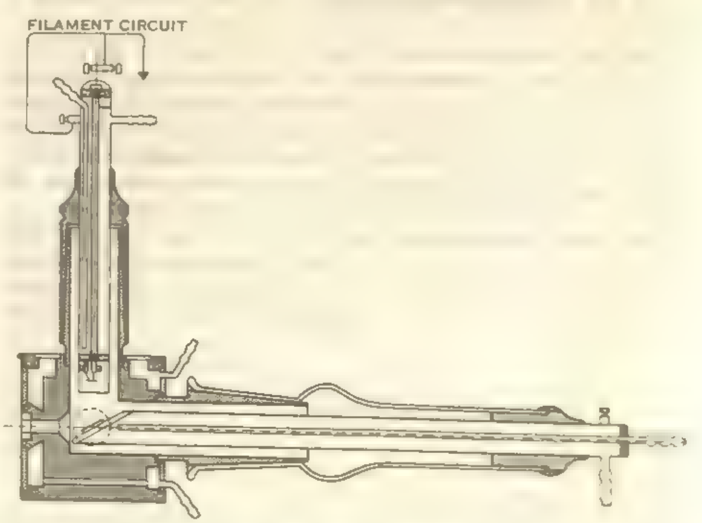

FIG. 7.—METAL X-RAY TUBE WITH HOT CATHODE FOR SPECTROSCOPIC USE

Different Kinds of X-ray Spectra.—The X-ray spectrum emitted from any substance is made up of two kinds of radiation, one of which shows a continuous distribution over a wide range of wavelengths, the other consisting of a few monochromatic rays overlapping the former (fig. 8). The first kind of radiation corresponds to the white light of optics, whereas the second is analogous to the line spectra. The continuous spectrum contains the greater part of the energy of radiation and is therefore the most important part for medical and other applications of X rays. This part of the X-ray spectrum shows qualitatively no dependence on the radiating substance, the intensity only being different from various anticathodes.

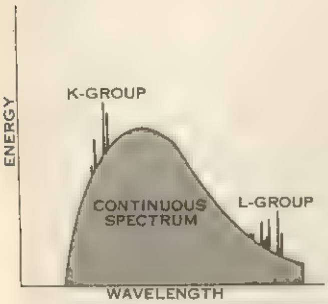

FIG. 8.—IDEALIZED X-RAY SPECTRUM SHOWING CONTINUOUS AND LINE-SPECTRA RADIATION

The line spectra on the other hand are characteristic of the emitting substance. They correspond to the K and L radiation of Barkla, but analysis has shown that each of these radiations consists of a group of monochromatic spectral lines.

The Continuous Spectrum.—The "white" or continuous radiation from an X-ray tube covers a rather wide region of wavelengths. The diagram of fig. 9 gives an idea of the distribution of the energy of the different wavelengths at X-ray tube voltages from 20 to 50 kv. The curves of distribution always start at a definite minimum wavelength (λ_{min}). The value of this wavelength decreases with increasing voltage. The wavelength (λ_{min}) or its corresponding frequency

$$\left(\nu_{max} = \frac{c}{\lambda_{min}}\right)$$

obeys the Einstein law

$$h\nu_{max} = eV \tag{2}$$

where e is the charge of the electron, V the voltage on the tube, and h Planck's constant. The amount eV is the energy received by the electron when accelerated by the voltage V. The most energetic radiation $h\nu_{max}$ in the spectrum occurs when all the electron energy is transferred to one X-ray quantum.

The energy eV of an electron or $h\nu$ of a radiation quantum is often expressed in the unit electron volt (ev). One electron volt is the energy of an electron (or another particle with the same charge) that has been accelerated by 1 v.

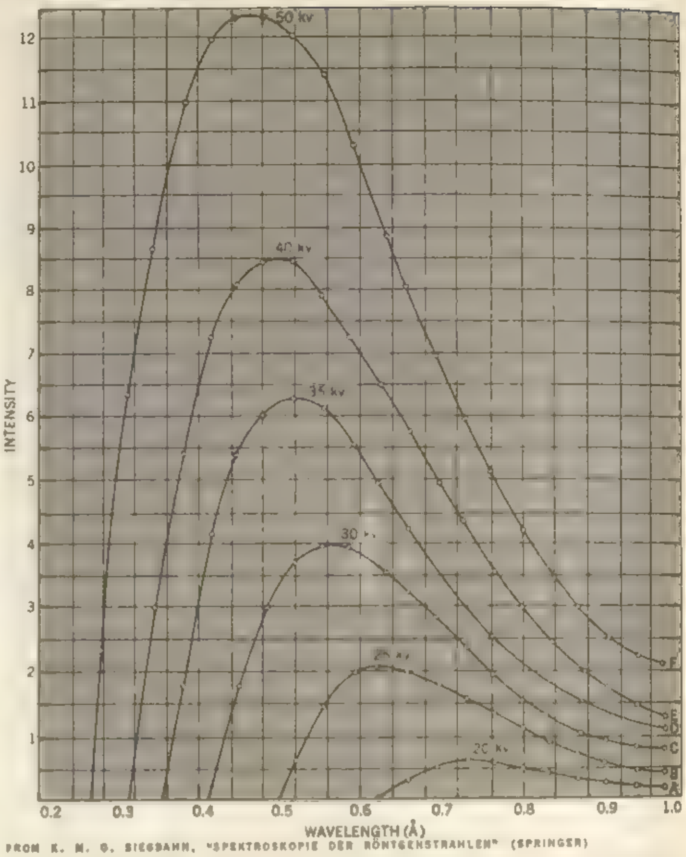
If the numerical values of e and h are introduced in equation (2) we obtain

$$\lambda\ \text{min} = \frac{12.3978}{V} \tag{3}$$

where the wavelength is expressed in angstrom units and V in kilovolts.

The total amount of energy (that is, the integral energy included by the distribution curves in fig. 9) is proportional to the square of the voltage on the tube, as has been verified by several investigators. Further, it has been found that for different elements used as anticathodes the total radiation is proportional to the atomic number of the element. For this reason, heavy elements have long been used as anticathodes in medical X-ray tubes.

The Line Spectra.—In 1913 and 1914 the young English physicist H. G.-J. Moseley published two remarkable papers in the *Philosophical Magazine* entitled "The High-Frequency Spectra of the Elements." Moseley showed that X-ray spectra include



FROM K. M. G. SIEGBAHN, "SPEKTROSKOPIE DER RÖNTGENSTRAHLEN" (SPRINGER)

FIG. 9.—INTENSITY DISTRIBUTION OF THE CONTINUOUS RADIATION FROM A TUNGSTEN ANTICATHODE AT VARIOUS VOLTAGES

line spectra of the same type as known in ordinary optics, and that these new spectra were built up in a more simple and regular way than is generally the case in spectra previously studied.

Two groups of spectral lines were found. One of these groups was identified with the K series of Barkla; the other, of longer wavelength and of more complex structure, corresponds to the L series. In 1916 M. Siegbahn discovered a new series of still longer wavelengths called the M series. The existence of series outside the K and L group had been suspected earlier by reasons of analogy. In the later development of X-ray spectroscopy, higher series, N, O, and so on, have been found.

A general scheme of the X-ray spectra is given in fig. 10, which contains the strongest lines of the three groups K, L, and M for every third element from sodium (11) to uranium (92). The diagram shows how all three series are regularly displaced to longer wavelengths as one proceeds from the heavier elements to the lighter. If the spectrum of some special element, say tungsten (74), a material commonly used for the anticathode, is considered, it will be seen that there are big gaps between the three groups where no lines are to be found. This fact is of predominant importance in interpreting the spectra in their relation to the structure of the atom.

According to the Bohr-Rutherford hypothesis, atoms are built up of a positive nucleus of comparatively small dimensions which is surrounded by a number of electrons. The electrons are grouped in definite shells formed by given numbers of electrons. Closest to the nucleus and most strongly bound are two electrons forming the K shell. The K shell is surrounded by the more loosely bound L shell, consisting of 8 electrons, and farther out is the M shell with 18 electrons at the maximum.

In an X-ray tube an electron hits an atom in the anticathode and knocks out an electron from one of its shells.

An energetic electron is able to remove an electron from the

FIG. 10.—THE STRONGEST LINES OF THE SEVERAL X-RAY SERIES ARE SHOWN FOR EVERY THIRD ELEMENT

K shell; in the case of tungsten the necessary energy is 69.51 kilo electron volts (Kev). The atom is now excited and contains the energy 69.51 Kev. The hole is filled immediately by an electron from an outer shell; *e.g.*, the L shell. The atom is now lacking one of its L electrons and contains the corresponding energy of 10.20 Kev. The energy difference 69.51 — 10.20 = 59.31 Kev is transmitted as an X-ray quantum $h\nu$ and the wavelength corresponding to 59.31 Kev can be calculated from equation (3) to be 0.209A (208.6 X.U.). If the hole in the K shell is filled by other electrons, other X-ray lines are obtained. They all have energies of the order of 60 to 70 Kev corresponding to 0.18 to 0.21 Å (178 to 213 X.U.). These lines form the K series of tungsten (fig. 6). A hole in the L shell involves an energy of about 10 Kev, and when this hole is filled up by transitions from the M, N, or other outer levels, the L series lines are emitted. The corresponding wavelengths are 1.2 to 1.6 Å (*see* fig. 10).

The transitions between the various energy states of the atom where different electrons are missing can be illustrated by an energy level scheme (fig. 11). The different levels are characterized by quantum numbers. The main quantum number n determines the various shells: K shell has $n = 1$, L shell has $n = 2$, etc. With one L electron missing, the atom is excited to the L level. An analysis shows, however, that the energy of the atomic excitation is dependent on which of the eight L electrons is ejected; in reality there are three different L levels, L_I, L_{II}, and L_{III}. Another quantum number l is now introduced. There are two L electrons with $l = 0$. If one of these electrons is missing, the atom is excited to the L_I level. The six other L electrons have $l = 1$, and the corresponding levels are L_{II} and L_{III}. The M shell with $n = 3$ gives rise to five levels: M_I ($l = 0$, 2 electrons); M_{II}, M_{III} ($l = 1$, 6 electrons); and M_{IV}, M_V ($l = 2$, 10 electrons). The building up of the electron configurations for some atoms (the noble gases) is given in the Table.

In fig. 11 some of the various transitions in the atom are represented by lines connecting the levels. The lines originating from the K level represent the K group, etc. (The four lines from the K level in fig. 11 correspond to the lines $\alpha_2\ \alpha_1\ \beta_3\ \beta_1$ in fig. 6.)

The electrons do not jump haphazardly from one level to another; the transitions are regulated by selection rules. The most easily occurring transitions, which give rise to the strongest lines, pass between levels where the quantum number l changes by one unit. The transitions noted in fig. 11 are some of the possible dipole lines. Other transitions are not strictly forbidden, but they give rise to very weak lines called quadrupole lines. Such a line is the KM_{IV}, KM_V line.

The Absorption Spectra.—In addition to the emission spectrum of X rays, there is also an absorption spectrum analogous to the absorption spectra of ordinary optics. Such spectra are obtained when a thin foil of some substance is placed between the X-ray source and the detector; *e.g.*, photographic plate. Instead of a continuous blackening from the white X radiation the photographic plate shows one or more sharp edges where there is rapid change in the blackening—the so-called absorption-edges.

These absorption discontinuities are explained as follows: An X-ray quantum $h\nu$ impinging on an atom may transfer its energy to a K or L electron, which will be ejected from the atom. To eject a K electron from a tungsten atom, an energy of 69.51 Kev is required, as mentioned before. This energy corresponds to a wavelength of 178 X.U. Obviously only quanta with an energy higher than 69.51 Kev (that is, radiation of wavelengths shorter than 178 X.U.) can eject K electrons. Radiation of wavelengths longer than 178 X.U. may pass relatively easily through a tungsten foil, but wavelengths shorter than the limit are strongly absorbed due to the process mentioned. When registered by a spectrometer, this results in a discontinuity in the intensity curve.

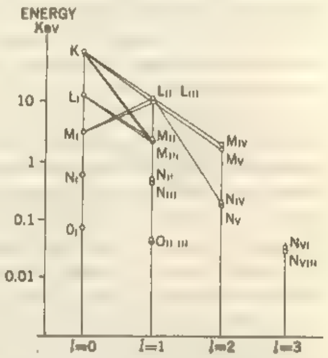

FIG. 11.—ENERGY LEVEL SCHEME FOR TUNGSTEN

Since the L shell has three energy levels, the L-absorption spectrum shows three discontinuities corresponding to the three levels L_I, L_{II}, and L_{III}. Fig. 12 shows an L-absorption spectrum together with the L-emission lines.

Ultrasoft X rays.—As already mentioned, the crystal grating method has its limitations in that wavelengths longer than double the distance between the atomic layers (say 10 or 20 Å) cannot be selectively reflected. This is clear from Bragg's law (equation [1]) which shows that λ cannot be larger than $2d$.

Fortunately it was found that ruled gratings when used in nearly grazing incidence gave nice spectra of the radiation with wavelengths down to the region where the crystals had their limits. This method was first used by R. A. Millikan for the optical spectra and then by A. H. Compton and R. L. Doan, M. G. Siegbahn, and others for the study of the ultrasoft X-ray spectra. An important result of this work was that it suggested a direct comparison between optical and X-ray wavelengths, resulting in a determination of atomic distances and the previously mentioned relation between the angstrom and X units.

Subsequently in this way a very exact determination of the value for the fundamental electric unit—the electronic charge—was worked out by Bäcklin. It was further possible to extend the different X-ray spectral series into the new wavelength region and to find lines belonging to the N and to the O series.

FIG. 12.—ABSORPTION AND EMISSION SPECTRUM SHOWING THE RELATIVE POSITIONS OF DISCONTINUITIES AND LINES

Miscellaneous Influences on X-ray Spectra.—The most striking difference between the ordinary optical spectra and the X-ray spectra is the fact that the former show a marked resemblance among elements with the same chemical character and change considerably from one group of chemically analogous elements to another, whereas in the X-ray spectra no indication of the chemical nature of the elements is to be found. This is readily explained by the Bohr-

Rutherford concept of the structure of the atom. From this interpretation, the optical spectra arise from the surface of the atom, which is also the seat of the chemical bonds, while the X-ray spectra are given off from the inner parts of the electronic atmosphere of the atom. It must, however, be expected that a small influence may be observed if an atom emitting an X ray is acted upon by neighbouring atoms. Determining the degree of this influence depends on the sensitivity and accuracy of methods used in studying X-ray spectra. By increasing the precision of study techniques, it has been possible to detect a number of such influences. It was first found by J. Bergengren that the K-absorption edge for phosphorus was displaced slightly when the element was modified. The line spectra are also influenced to a certain degree by the chemical bonds. *See* also QUANTUM MECHANICS; RADIOACTIVITY; RADIOLOGY; SPECTROSCOPY; X RAYS.

See B. D. Cullity, *Elements of X-ray Diffraction* (1956); A. Guinier, *X-ray Diffraction in Crystals. . . .* (1963). (M. SIE.)

SPEECH AND LANGUAGE, in psychology, present a set of ancient problems. Plato set one such question in his dialogue *Cratylus*: ". . . Cratylus has been arguing about names; he says that they are natural and not conventional; not a portion of the human voice which men agree to use; but that there is a truth or correctness in them, which is the same for Hellenes as for barbarians." Many centuries of argument added little to Plato's discussion of symbolism in language until a simple 20th-century experiment gave it new life.

People were asked to match words from their own language with those from another that was completely unfamiliar to them; speakers of English, for instance, were given the antonyms small-large and the unfamiliar equivalent pair from Chinese, *ch'ing-ch'ung*. Nearly 90% of those tested guessed correctly that large means *ch'ung* and small means *ch'ing*. If there were nothing in the sound of the foreign words to suggest the translation, by chance about 50% would be expected to guess correctly. Many such experiments have been conducted and, while improvement over chance performance is generally very small, the evidence suggests that parts of many languages do share a principle of correctness "which is the same for Hellenes as for barbarians."

New experiments and developments in research technology, structural linguistics, and information theory have shed light on many other aspects of psychology and language (*see* INFORMATION THEORY; LINGUISTICS). These include the recognition of speech, determinants of word association, the nature of meaning, the way children learn their native language, and the relation between language and thinking.

Recognition of Speech.—The sound spectrograph provides detailed visible records of the acoustic properties of speech sounds (*see* VOICE: *Methods of Investigation*). Such records (spectrograms) have been used in the search for acoustic cues that permit recognition of given vowels or consonants regardless of the speaker. The relative importance of each cue is then investigated by painting artificial spectrograms and converting these visual patterns into synthetic speech that listeners are asked to identify. Such studies show that cues for recognition are found primarily in the two or three most intense formants (frequency regions of the greatest acoustic energy), in the formant transitions between consonants and vowels, in the frequencies of the bursts in the release of stop consonants, and in the durational aspects of certain sounds (*see* PHONETICS: *Phonetic Description*). The work of R. Jakobson (*q.v.*), M. Halle, and their collaborators suggests that cues to recognition in any language may be very economically described in terms of a small number of acoustic features. Such progress has led to electronic equipment (*e.g.*, the "Voder") that produces recognizable speech (*see* ROBOT); by the 1960s experimental devices could recognize spoken sounds, heralding such applications as a voice typewriter and a telephone for the deaf.

In ordinary experience some sounds occur with relatively high frequency, and people approach the task of recognition with a set of weighted expectancies. A syllable like *srate*, which does not occur in English, is less likely to be correctly identified than is a word like crate. Visual presentation of a form like *vernalit* (which technically approximates English in terms of information theory) is more likely to elicit recognition among English speakers than is a form like *ozhgpmtj*.

Word Association.—In the word-association experiment a subject is presented with a stimulus word (*e.g.*, hot) and asked to provide a response word (*e.g.*, cold). The period of time between the two is called the response latency. After its invention by Sir Francis Galton, the experiment was applied to psychiatric diagnosis and to the detection of lies and guilty knowledge in criminology. A subject's immediate response may be revealing in an obvious way, or an unusually long latency may indicate that such a revealing response has been deliberately suppressed.

The usual determinants of an associative response are habits based on ordinary language usage (as are the weighted expectancies that affect recognition). The probability of a particular response word is related to how frequently the word occurs in speech and writing, and how often it follows the stimulus word in ordinary usage. The word counts of E. L. Thorndike (*q.v.*) and I. Lorge are commonly used compilations of such data from printed materials.

In 1910 G. H. Kent and A. J. Rosanoff published the responses of 1,000 adults to 100 English words; several sets of word-association norms have appeared since. The most popular (primary) response tends to be given by a large percentage of subjects (*e.g.*, 65% gave "light" in response to "lamp" in the Kent-Rosanoff study), the list trailing off with many responses given only once. J. J. Jenkins and W. A. Russell, who published the University of Minnesota word-association norms (1954), compared sets of data collected since 1910 and found an increasing proportion of popular responses. This may be a result of greater uniformity in usage arising from the growth of mass media communication.

Language associations also have been studied through verbal conditioning; in one type of experiment a word is presented along with the sound of a loud buzzer. The buzzer tends to elicit a change in the electrical resistance of the subject's body (*see* PSYCHOGALVANIC REFLEX). After several repetitions the reflex occurs in response to the word alone (*see* CONDITIONING). The varying intensities of the reflex in response to associated words have been used to infer the implicit verbal associations of the subject. Extensive use of the method in the Soviet Union and the U.S. has shown, for example, that young children tend to exhibit a generalized reflex to words that sound alike (*e.g.*, earn-urn); adults are more likely to generalize to words of similar meaning (*e.g.*, urn-vase).

Meaning.—One way to find out if someone knows the meaning of a word is to ask him for a definition or synonym as in verbal intelligence testing. Or, the person can be asked if the word applies to this or that referent object. J. Piaget, for example, in studying how children understand the word "alive" asked whether a dog is alive, a table is alive, and so on (*see* CONCEPT FORMATION, PSYCHOLOGY OF; MEANING; SEMANTICS IN LINGUISTICS). These methods are concerned with the central literal meaning of a word.

The semantic differential, developed by C. E. Osgood and others, is a technique designed to assess subtler aspects of meaning. This work began with efforts to identify basic dimensions of connotative meaning in English. In a typical study subjects were given a list of 20 assorted words (*e.g.*, lady, boulder, sin) plus 50 seven-point rating scales with extremes labeled as good-bad, light-heavy, red-green, sweet-sour, active-passive, and so on. The task was to place each of the 20 words on each scale. Although some of the required judgments were prosaic (*e.g.*, deciding whether boulder is light or heavy), the scales often lacked literal application (*e.g.*, is sin red or green?). Many scales were found to function as near-synonyms, with judgments on one being highly predictable from those on another. Statistical treatment of the data with a method called factor analysis revealed three major independent dimensions identified as evaluation, potency, and activity. Similar studies (including some with other languages) have yielded the same dimensions, permitting economical measurement of meaning through a few scales selected to represent each major dimension. Most commonly, four scales are used to represent evaluation (usually including good-bad); three to represent potency (usually including strong-weak); and three for activity

(usually including active-passive). Semantic differential measures of meaning have been widely applied, particularly to the study of social attitudes, experimental aesthetics, in consumer research, and in evaluating the effects of psychotherapy.

Children's Speech.—A very large part of language is learned in the typical child's first three years. Babbling in the first year and a half often includes sounds not used in the parental language (*e.g.*, umlaut vowels for an infant in an English-speaking household) and those the child later may have difficulty articulating (*e.g.*, [l] and [r]). Vowels predominate over consonants in babbling, and studies of early vocalization (O. C. Irwin and others) indicate that front vowels (*e.g.*, [I] as in hid) tend to appear before back vowels (*e.g.*, [o] as in blow); the first consonants are likely to be velar and glottal sounds formed in the back of the throat (*e.g.*, [g] as in good). Imitation of adult sounds tends first to appear about six months of age; the first intelligible word commonly at about the end of the first year; and simple sentences near the end of the second year. Although normal children may vary widely from this schedule, maturation does tend to set a timetable for human speech development.

Children's understanding of word and sentence meaning shows a long and complex development. L. S. Vygotsky and Piaget have shown that children at first conceive of the relation between words and referents as natural and unalterable rather than as local conventions. O. Jespersen, H. Werner, and many others have shown that a child often overgeneralizes in his first use of words; for example, calling all male adults "daddy" or all quadrupeds "doggie." Piaget has traced the development of understanding of the complex concepts associated with such words as "because," "although," and "more."

A terminal linguistic achievement is the ability of children to produce sentences they have never heard but that are meaningful and grammatical. The child learns to use a grammar or a set of rules (which he cannot explicitly state) for the combination of words. Studies of children learning Russian (K. Chukovsky), French (P. Guillaume and A. Grégoire), and English (J. Berko) show that children at first operate with a simply regular grammar. Children learning English, for instance, are likely to say "digged" and "ringed" rather than "dug" and "rang," or "gooses" rather than "geese." The rules of adult English involve many qualifications and exceptions, and young children treat the language as if it were a more simply consistent system than it is.

Thinking.—It is popularly believed that all normal people are aware of reality in much the same way and that languages are simply conventional vehicles for thinking and play no part in its formation. A very different view (E. Sapir, B. L. Whorf) holds that the same reality can be variously conceived and that each language embodies and perpetuates a particular conception.

There is very little evidence of a direct effect of language on thinking, but countless examples of linguistic differences strongly suggest a parallel difference in thought processes. Numerous languages have a single word for the colours green and blue. Eskimo have words for many more varieties of snow than do Europeans or Americans. The Hanunóo people of the Philippine Islands have 92 names for what an English-speaking layman would call simply rice. From many such examples the fineness of differentiation in vocabulary seems to increase with the importance of the given referent field to the speakers of a language. People whose language fails to make a given distinction are probably less likely to think and perceive in such terms than are those whose language does. It seems likely, however, that the distinction can be learned if it becomes important and that the influence of the native language is not irrevocable.

SPEECH DISORDERS. Speech may be said to be disordered, and so to present a problem for the speaker, or his listeners, or both, when listeners pay uneasy attention to the manner of speech, have difficulty making it out, or are distracted from what is said by the way in which it is said. The major personal effects of speech disorders depend on the basic role of speech in human relationships. Insofar as such disorders interfere with ability to relate to others through speech, and so to achieve social and personal adjustment, they affect personality. Some authorities regard certain kinds of speech disorders as symptoms of emotional disturbance or personality maladjustment. Research evidence, however, indicates that while most persons with speech disorders have educational, vocational, social, and personal problems because of impaired speech and because of their own and other people's reactions to it, as a group they do not significantly differ in basic personality from persons without speech disorders.

So few estimates of prevalence of speech disorders in different countries are available that meaningful comparison is impossible. Further, available estimates reflect cultural differences in the value attached to quality of speech, especially in small children. Substantial data indicate that among the Ute, Bannock, and Shoshone Indians of North America, as well as in certain cultures in other parts of the world, lack of fluency in children is uncritically accepted and the problem of stuttering does not occur. On the other hand, in modern Western cultures, the strong trend toward "standard speech," enhanced by radio and television, encourages conformity and so directs attention to unusual or disordered speech. It seems likely that, other things equal, the more value a society attaches to "correct" or "normal" or "good" speech, the larger will be the proportion of its members regarded as having disordered or unsatisfactory speech.

The United States Office of Education has variously estimated that 3% to 4%, or roughly 2,500,000, of school-age children in the United States have speech disorders. For the rest of the population, an extremely conservative figure is 3%, or close to 5,000,000. This gives a national total of roughly 7,500,000 speech-handicapped persons. Office of Education statistics indicate further that speech impairment is the commonest handicap in U.S. school-age children: of the 105 out of every 1,000 that are handicapped in some way, 35 have speech disorders, 23 are mentally retarded, 20 are emotionally disturbed, 10 are physically disabled, 10 have handicapping illnesses, 6 have hearing problems, and 1 is blind or partially seeing.

Speech pathology and audiology have developed as a theoretical and clinical service field in the United States. Clinical work with speech disorders (usually in closer relationship to medicine than it is in the United States) is fostered also in Great Britain, the Scandinavian countries, most of the rest of continental Europe including the U.S.S.R., Japan, South Africa, South America, and such parts of the British Commonwealth as Canada, Australia, and New Zealand. There is promising evidence that as teachers, physicians, and parents learn more about how, for example, stuttering begins, its prevalence is decreasing; and that new modes of treatment of stuttering in its early stages, stressing counseling of parents and teachers, are increasingly effective. There is compelling evidence that most children who misarticulate speech sounds can be taught to form the sounds normally; that most voice problems yield to treatment; that most patients who undergo laryngectomy (surgical removal of the "voice box") can learn to speak again; that patients with aphasia recover useful language and speech. Such organic impairments as cerebral palsy, severe hearing loss, and cleft palate, however, even with all possible physical restoration, in some cases set limits to speech improvement. Nevertheless, persons without tongues have learned to speak, and the large numbers of persons with cleft palates who speak normally or nearly so reflect recent advances in surgery, prosthetic and orthodontic dentistry, and speech pathology and audiology.

DESCRIPTION, CAUSE, AND TREATMENT OF SPEECH DISORDERS

Classification Schemes.—Disorders of speech are commonly classified as follows: (1) disorders of voice; (2) disorders of

articulation; (3) stuttering (stammering); (4) aphasia (dysphasia); (5) retarded development of speech or language; and (6) speech disorders associated with hearing loss or deafness, cleft lip and cleft palate, cerebral palsy and other neuromuscular impairments, laryngectomy, facial or oral injury or deficiency, mental retardation, and emotional illness.

There are other classification schemes. Some speech pathologists add a category called cluttering, usually said to be distinguished by rapid rate, indistinct articulation, and some disfluency, but without the tension, anxiety, and blocking reactions that characterize stuttering. The definition and clinical significance of "cluttering" are in process of clarification. A controversial diagnostic category is "congenital" aphasia, referring to a condition said to be due to brain deficiency or to brain damage before, during, or after birth but before development of speech. "Congenital" aphasia is not universally accepted because some insist that there can be no aphasia if there is no developed language function to be lost. The controversy is complicated by the difficulty in most cases of clearly demonstrating brain damage. "Retarded speech or language development" is a more widely accepted diagnostic term.

The Total Speech Problem.—In presenting, below, descriptions, causes, and treatments of the various speech disorders (*see* MOUTH; VOICE; and EAR, ANATOMY OF, for anatomical details mentioned), each disorder is considered to be ono part of a total speech problem; each such problem has as participants not only the speaker but also his listeners. Some listeners contribute to solving or coping with the problem, others make it worse. Some even help to cause it in the first place, as, for example, in the beginning of stuttering, when the child's hesitations and repetitions appear to his parents to be a problem before they do to the child.

The total speech problem has three aspects: first, the speech characteristic that is regarded as a disorder; second, the listeners' reactions to the speech; and third, the speaker's reactions to the listeners' reactions and to his own speaking behaviour. Listeners' revealed feelings—and in the case of children the most important listeners often are the parents—about speech affect the speech, making it more or less hesitant, disfluent, or tense. The speaker's reactions to the listeners' reactions may thus either complicate the disorder or help in the direction of more acceptable speech.

The three aspects of the speech problem may be affected by various factors: the speech characteristic itself may be complicated by such organic conditions as cleft palate, dental malformations, or brain damage, or by such nonorganic factors as poor adult speech models and lack of stimulation and motivation. Listener and speaker reactions may be affected by level of education, intelligence, experience with and understanding of speech disorders, and personal and social adjustment. Listener and speaker reactions of course vary. What one listener hears as severe disfluency, another may regard as moderate and a third as normal for age and circumstance; likewise, the speaker may be unconcerned or moderately or deeply concerned about listener reactions and about the speech characteristic to which they are related.

Diagnosis and Therapy.—For any type of speech disorder, diagnosis involves: (1) detailed description of what the speaker does that makes his speech clinically significant; (2) identification of the times, places, listeners, and types of speaking in relation to which he does or does not do these things; and (3) determination of whether physiological or psychological factors are fostering the disorder.

Basic aspects of therapy include: (1) identifying the persons other than the speaker who are most concerned in the problem, counseling them, and enlisting their support; (2) making use of family, school, and community resources; (3) counseling the speaker as his age and maturity warrant; (4) speech retraining by individual or group methods that enable the speaker to hear, see, and feel what he does that interferes with his speech; to listen to the differences between disordered and normal speech patterns; to practise the normal patterns, or his best approximation of them, in drill sessions and increasingly in social situations Tape recorders, mirrors, sound amplifiers, and other instruments and positive rewards and reinforcements are useful in facilitating the desired learning. In any case of impaired speech associated with physical or psychological factors—as, for example, misarticulations related to mouth injury, cleft palate, or cerebral palsy, or speech impairment related to emotional illness or loss of hearing—appropriate medical care or psychological counseling should precede or accompany speech therapy.

Disorders of Voice.—The voice may be pitched too high or too low; may be too loud or too soft; may be distractingly nasal, hoarse, harsh, or breathy; or may lack expressive variation. The voice may be affected by enlarged tonsils and adenoids, throat infections, the common cold, vocal abuse, growths on the vocal cords, and paralysis. Most voice disorders, however, are associated not with organic pathology but with negative emotional reactions (resentment, hostility, anger, or shame), faulty models for learning speech, shyness and insecurity, or adolescent "change of voice." In speech therapy, ear training may be emphasized for monitoring pitch, loudness, quality, and flexibility. A change of pitch level may be prescribed to reduce tension and increase expressiveness.

Disorders of Articulation.—About 80% of the children in public-school remedial speech programs in the United States have disorders of articulation. Often these result from faulty learning due to meagre speech stimulation or from inadvertent positive reward by parents through their acceptance of speech with such errors. It is an unresolved question whether many of these children, concentrated in the early grades, would learn to articulate correctly in the normal course of maturation. Practically all articulation errors are omissions of speech sounds (as in *pay* for *play*), distortions of sounds (slighting sounds or overarticulating them, as in the "whistling" *s* or in the "mushed" *s* that resembles *sh*), or substitutions of one sound for another (as *wun* for *run* or *thum* for *sum*). A speaker may misarticulate one or more sounds or sound blends (as *st*, *pl*) consistently or inconsistently.

Speech retraining is concerned chiefly with the defective sounds. If the speaker is a child still learning to speak and making the errors common for his age, he may need no speech instruction; the clinician works instead with the parents, teachers, and other listeners to encourage normal maturation of the child's speech.

Stuttering (Stammering).—Stuttering, like all disorders of speech, is not concerned with the speaker alone. The characteristic to which his listeners originally react is disfluency, as seen in repetitions, "uh uh," hesitations, and interruptions common in normal childhood speech and occurring also in normal adult speech. Half or more of all parents do not notice their young children's disfluencies. Most parents who do notice them regard them as normal. Roughly one parent in 100 reacts with serious concern. Sensing this reaction, the child may gradually come to doubt that he can speak well enough to please his parents, and to fear the consequences if he does not. As he tries harder to speak more fluently than he can, he becomes less spontaneous, more hesitant, tense, and uneasy. Straining to do better, he presses his lips together, holds his breath, and performs other actions that interfere with speech. He has more difficulty speaking; his parents become still more concerned. They try to be helpful by urging him to relax, go slowly, start over; he feels more discouraged and becomes more tense and distressed. And so stuttering develops.

The single question "What causes stuttering?" therefore breaks down into four questions: (1) Why does one parent in a hundred make a serious issue of the child's disfluencies? (2) What causes the disfluencies? (3) How are they complicated by speech-disorganizing reactions? (4) Why does the speaker react negatively to his disfluencies and to his listeners' negative reactions to them —and to him? With regard to (2), some speech pathologists hold that the disfluencies are caused by organic factors, including heredity, while others view them as symptoms of emotional disturbance, usually involving impaired parent-child relationships; but laboratory and clinical data do not firmly support these hypotheses. Another explanation is that simple disfluencies are part of the normal speech process, varying with such factors as age, language development, momentary excitement, and listener in-

terest; the child learns speech-disruptive behaviour as he tries to keep from stuttering and so to gain approval.

For a young child, treatment is directed mainly to the parents and other listeners important to the child, who are counseled to increase their understanding of the factors, including their own reactions, that affect the child's disfluencies; to help them understand how the problem is compounded by the child's misguided efforts to speak more clearly; to encourage them to make it easy for him to talk to them; and to provide conditions favourable for his spontaneous attempts at speech. Older children and adults are given much the same sort of counseling as key listeners, being treated clinically as both listeners and speakers. They are trained to think about what they do that interferes with speaking rather than about what happens or what it is that prevents the words from coming out. Once the stutterer recognizes what he does that disrupts his speech, he works to increase his awareness of it and to contrast it with his normal speech. Therapy proceeds then toward learning or relearning to talk without exerting the tensions and doing the other things that disrupt speaking.

Retarded Development of Speech or Language.—Development of speech or language may be retarded in respect to: (1) amount of vocalizing during infancy, (2) age at which first words and sentences are spoken, (3) articulation of speech sounds, (4) length and complexity of speech response, (5) amount of speaking, and (6) vocabulary. A child's speech development is to be compared not with any average (though speech development norms have been presented) but with that of the majority of children and with his own past performance. Generally speaking, a child may be a year behind the majority without being considered retarded. In the United States, for example, where most children have begun to say words at the age of 12 to 15 months, a child would not be judged retarded until he had passed 24 months without doing so. Factors commonly associated with retarded speech development include lack of speech stimulation in the home; inadequate or inconsistent rewards and punishments; isolation and inactivity, as in prolonged illness; impairment of muscles used in speech; damage to the brain; and loss of hearing.

Aphasia (Dysphasia).—Aphasia, or more appropriately dysphasia, is the impairment of language function due to brain damage. Loss of language function may be slight to total and is likely to be regained as, and in the measure that, the patient recovers from the condition that caused it. Recovery may be hastened or enhanced by speech therapy. Speech retraining is based on remaining functions and life experience with language. A patient relearns best the language concerning things with which he was once familiar and thus in all likelihood will make best progress in familiar surroundings. Objects and pictures are shown, the patient repeats the names, points to them, then uses them in phrases and sentences.

Speech Disorders Associated with Other Physical or Mental Disorder or Impairment.—*Impaired Hearing.*—Hearing loss may be slight, moderate, or severe and varies in character. (*See* DEAFNESS AND IMPAIRED HEARING.) For a person with simple conductive hearing impairment, all voices are muted except his own, which sounds louder to him than it does to his listeners. His main or only speech problem lies in speaking loudly enough. Other types of hearing impairment may result in a variety of distortions of hearing: the person may hear his own and others' voices as muted, hear low-pitched sounds better than high-pitched, hear some things and not others. When two kinds of hearing loss occur together the associated speech problem usually reflects the combination. The speech and language difficulties of hard-of-hearing persons therefore may be complex. The afflicted person may have a limited vocabulary or may misarticulate certain sounds; his voice may be unusually loud, monotonous in pitch, and muffled in quality as if the mouth were full. Therapy emphasizes monitoring speech, training in the use of a hearing aid if the patient can benefit from it, practice in the recognition of sounds, training in lip-reading (or speech-reading, as it is more appropriately called), and vocabulary building. Young children with profound hearing impairment tend not to learn speech unless taught by special methods in schools for the deaf (*see* DEAF AND HARD OF HEARING, TRAINING AND WELFARE OF).

Cleft Lip and Cleft Palate.—Clefts of the upper lip or the palate (roof of mouth), or both, are formed, for reasons not well understood, when normal growth is disrupted early in fetal life. A cleft may involve only the soft palate or both soft and hard; may extend through the front upper gum ridge; and may involve one or both sides of the upper lip. Cleft lip is usually repaired surgically shortly after birth, and if there is no other cleft no speech problem is likely to develop unless there remains a limitation of lip function that affects articulation of lip sounds. Cleft palate may be closed surgically or by means of an obturator (artificial palate). An obturator must be adapted periodically to the child's growth; surgery should wait until the age at which it will not interfere significantly with growth of the upper jaw and the face. After palatal closure, most children, at least in the United States, require speech training to counteract excessive nasality, misarticulations, inefficient regulation of air pressure within the mouth, and in some cases vocal monotony, low loudness level, indistinctness, and lack of spontaneity. Training to correct faulty jaw and tongue action may be started even before closure has been made.

Cerebral Palsy and Other Neuromuscular Impairments.—Paralysis (*q.v.*) impairs speech when it affects muscles used in speaking. Cerebral palsy (*q.v.*) affects these muscles in about three out of four cases, producing laborious and slow speech, of uneven rhythm, with breathing irregularities, faulty articulation, and monotonous or erratic patterns of voice quality, pitch, and loudness. The speech problem is often only one of several associated with this condition. Treatment of cerebral palsy requires the resources of medicine, special education, physical and occupational therapy, psychology, social work, and speech therapy.

Laryngectomy.—Laryngectomy, most commonly performed in later life as a means of controlling cancer, leaves the patient without vocal cords. Though he cannot vocalize, usually he can learn esophageal speech, drawing air into his esophagus, producing sound as he expels it, and articulating this sound into spoken words. An "artificial larynx" also may be used (*see* VOICE: *Substitutes for the Larynx*).

Facial or Oral Injury or Deficiency.—Problems of articulation and occasionally of vocal resonance and quality may be associated with high and narrow hard palate, large or sluggish tongue, surgery of the tongue, cancer, and missing or misaligned front teeth. Following dental and medical treatment, speech therapy is indicated.

Mental Retardation.—Learning difficulties of the mentally retarded extend to learning to speak, misarticulations being the main speech problem. Retraining methods are adapted to specific needs and abilities, with emphasis on simplicity, persistence, patience, and rewards for small gains.

Emotional Illness.—The chief effects of emotional illness on speaking behaviour are restrictions or disturbances of speech, impairment of voice, and deviant use of language. Often the voice is high pitched, nasal, harsh, and monotonous; or the patient may not speak at all. Treatment usually begins with a psychological evaluation. Speech therapy and psychotherapy may then proceed together, in a relationship that depends on whether the speech problem preceded, is independent of, or is basic to the personality problem.

DEVELOPMENT OF SPEECH CORRECTION

Persons with speech disorders, like other handicapped persons, have traditionally known the scorn, ridicule, and even revulsion of their society. Attitudes toward handicaps have changed only slowly, and the change is still going on. Hippocrates (fl. 400 B.C.) was among the first to look at speech disorders scientifically, writing a treatise on the cause of stuttering. Other early scientists who were interested in speech and speech problems included Albertus Magnus, who in the 13th century wrote about voice pitch and articulation; Paracelsus, who in the 16th century referred to speech disturbance after injuries to the head; Hieronymus Mercurialis (Geronimo Mercuriale), who published (1584) on children's speech; and J. C. Ammann, whose *Surdus loquens* (1692) set down the oral method of training deaf children. By the 19th century a large European medical literature on speech was de-

veloping, and concurrently in the New World the work went on through activities of such men as T. H. Gallaudet, who had been schooled in London and Paris. The Spanish singing teacher Manuel García at mid-century developed a method for examining the larynx; the French surgeon-anthropologist Paul Broca in 1861 published his pioneer work relating aphasia to brain lesions; H. Klencke, in Leipzig, was the first formally to suggest (1862) that effective speech correction must deal with the total speech problem; C. L. Merkel's *Anthropophonik* ("Human Phonetics") in 1876 and Adolf Kussmaul's *Die Störungen der Sprache* ("The Impediments of Speech") in 1877 stand as classics from which German logopedics grew.

By the early years of the 20th century, with the growth of knowledge about speech, with refinement of clinical techniques in speech correction, and with new appreciation of the human need to communicate, there emerged an interdisciplinary profession which in the United States went by the name of speech pathology and audiology and in Europe was called logopedics and phoniatrics. The contributing professions included medicine, psychology, dentistry, education, speech, psychiatry, engineering, and social welfare. All are represented in the membership of the International Association of Logopedics and Phoniatrics (IALP) and of the American Speech and Hearing Association (ASHA), two of the more inclusive organizations in the field. Both were founded in the 1920s; both are dedicated to support of high professional standards, encouragement of research, and improvement of clinical procedures.

Most countries of Western Europe have some kind of provision for speech correction, but programs and requirements for the training of speech correctionists vary. Much of the program is directed by medical doctors, often in hospital clinics or special schools. As compared with procedures in the United States, the initial evaluation of each case is considerably longer, use of speech stimulation techniques and motivational devices is considerably less.

Great Britain, with a long history of speech correction, officially recognized speech disorders as a handicap by the Education Act, 1944. The College of Speech Therapists, an organizing and examining body, was established in 1945; the first school for children with very severe speech handicaps was opened in 1947.

Japan, with schools for the blind since the 8th century and for the deaf since the 19th, is developing a school-connected program in speech correction with the assistance of therapists and clinicians who are largely self-taught and with the support of a research program.

In the U.S.S.R. speech correction is directed by the Department of Logopedics in the government Institute of Defectology of the Academy of Pedagogical Sciences. Children with speech disorders go to regular schools; each school has at least one logopedist, who works often with other specialists. Therapy may include repetition of sounds, long periods of silence, use of the logopedist's finger or a wire apparatus called a zond to place the tongue properly for a given sound. The child is encouraged to assume much responsibility in overcoming his handicap.

In the United States, 200 colleges and universities offer degrees in speech pathology and audiology, 25% at the doctoral level. The M.A. degree is required by the American Speech and Hearing Association for membership and for clinical certification of speech correctionists. Many states, as well, set certification requirements. There are about 7,000 active speech correctionists, most of them in public schools, some in community clinics or with special health agencies, some staffing the 320 speech and hearing clinics associated with hospitals, colleges, and universities. About one-fourth of the children who have some kind of speech disorder are receiving special speech training.

SPEED, JOHN (1552?–1629), English antiquary and cartographer, whose *Theatre of the Empire of Great Britain* (1611–12; titlepage 1611) was the first printed atlas of the British Isles. The son of a tailor, he was born at Farringdon, Cheshire, and became a tailor in London, but in 1598, through Fulke Greville's patronage, received a royal sinecure. This gave him leisure for his topographical and historical researches, and, helped by Sir Robert Cotton, William Camden, Sir Henry Spelman, and other fellow members of the Society of Antiquaries, he published (1608–10) a series of county maps of the British Isles and gathered material for his *History of Great Britaine . . . from Julius Caesar to . . . King James* (1611). To this the *Theatre*, in which the maps were collected, formed a prologue.

In 1626 he published the first English general atlas, *A Prospect of the Most Famous Parts of the World . . . Asia, Africa, Europe, America*. Like the *Theatre*, this was very popular, and both were frequently reprinted, sometimes, as in 1676, combined in one volume. Another popular work was his *Genealogies Recorded in Sacred Scripture*. Despite blindness, Speed continued to revise his *History* until his death, in London, on July 28, 1629.

Although his *History* was admired and is of interest for including valuable records, *e.g.*, lists of the abbeys dissolved by Henry VIII, it is mainly based on earlier work, as its author acknowledged. Speed's maps, too, are based on those of earlier cartographers; their importance consists in their innovations. His additions to the maps of Christopher Saxton and John Norden (*see* MAP) resulted from his own journeys; he added inset town plans and showed his interest in history by recording antiquities—forts, castles, battle sites, earthworks, etc. His *Theatre* remained influential until the 19th century, and his maps are still of historical interest.

See R. A. Skelton, *Decorative Printed Maps of the 15th to 18th Centuries* (1952); E. Lynam, *The Mapmaker's Art* (1953).

SPEEDOMETER, an instrument that indicates the speed of a vehicle; usually, it is combined with an odometer, which records the distance traveled. The speed-indicating mechanism of the speedometer is actuated by a permanent magnet rotated at a speed of 1,000 revolutions per mile of vehicle travel by a flexible shaft driven by gears at the rear of the transmission. The magnet turns within a "speed cup" made of a light, nonmagnetic metal, such as aluminum, and the magnetic circuit is completed by a circular stationary field plate surrounding the speed cup.

The rotating magnetic field passing through the metal of the speed cup induces eddy currents that increase with the magnet speed and set up a proportional magnetic field attracting the speed cup to the rotating magnet, tending to rotate it against the restraint of a coiled hairspring. The torque acting on the speed cup is proportional to the eddy currents and thus to the rotational speed of the magnet. The speed cup turns until the restraining torque of the hairspring, increasing with the angle through which the cup turns, equals the applied torque. The angular position at which the speed cup comes to rest varies directly with the rotational speed of the magnet and hence with the speed of the vehicle. The speed cup may have a scale of miles (or kilometres) per hour on its periphery that is visible through a small window, or it may have a pointer attached to it that moves across a graduated scale.

The odometer, which registers the distance traveled by the vehicle, consists of a set of figure wheels, usually from four to six, arranged along a cross shaft and turned by a series of star pinion gears located inside the drum formed by the figure wheels. A train of intermediate gears connects the figure wheel at the right to the magnet shaft at a gear ratio of 1,000:1, causing it to complete one turn per mile. Its numerals thus indicate tenths of a mile.

The figure wheels are so geared together that, as one wheel completes a revolution, it turns the figure wheel next to the left one-tenth of a turn, thus summing up the miles traveled. A "trip odometer" is sometimes included that is provided with a reset mechanism to return it to zero. (O. C. C.)

SPEKE, JOHN HANNING (1827–1864), English explorer who solved the mystery of the Nile sources by his discovery of Lake Victoria, was the first European to visit Uganda. He was born May 3, 1827, at Orleigh Court, Bideford, Devon. Commissioned in the Indian Army in 1844, he served in the Punjab and traveled in the Himalayas and Tibet. In 1854 he joined an expedition to explore Somaliland under the command of Richard Burton (*q.v.*). This venture was wrecked at the outset in an attack by Somalis outside Berbera in April 1855 during which Speke was severely wounded. In 1856 Speke joined Burton on a Royal Geographical Society expedition to investigate the great lake said to lie at the heart of Africa and to be the source of the Nile. They arrived in Zanzibar in December 1856 and left for the interior from Bagamoyo on June 27. They reached Tabora (or Kazé) by the Arab trade route on Nov. 7 where they learned of the existence of three great lakes (Nyasa, Tanganyika, Victoria), and, although in ill health, they pressed on to Ujiji on Lake Tanganyika, where they arrived in February of 1858. Back at Tabora in June, Speke struck north alone to find the lake he guessed was the source of the Nile, and this he reached and named Victoria on July 30. Speke returned to England first and announced his discovery of the Nile source; his conclusions were disputed later, and Tanganyika suggested as the source. Sir Roderick Murchison, president of the Royal Geographical Society, supported Speke who received the Founder's Medal. He was invited to lead another expedition to confirm his findings and chose James Grant to accompany him. Leaving Zanzibar in September 1860, they reached the southwestern shore of Lake Victoria, via Tabora, a year later. Speke pressed on ahead up the west shore into Buganda, arriving at King Mtesa's capital (near Kampala) on Feb. 19, 1862. He marked the Nile's exit from the lake by naming the Ripon Falls on July 28. Speke and Grant then tried to follow the course of the Nile but were checked by civil war in Bunyoro. They reached Gondokoro on Feb. 15, 1863, and met (Sir) Samuel and Florence Baker, to whom Speke gave directions for finding the lake in Bunyoro through which he guessed the Nile must flow. He described his adventures in *Journal of the Discovery of the Source of the Nile* (1863) and *What Led to the Discovery of the Source of the Nile* (1864).

On his return to England, Speke's claims were again challenged. A discussion between him and Burton was arranged to take place at the British Association at Bath in September 1864, but, while the audience waited, news was brought that Speke had been found killed accidentally by his own gun while shooting at Neston Park, near Corsham, Wiltshire, on Sept. 15, 1864.

Grant, *A Walk Across Africa* (1865); S. W. Baker, *The Albert N'yanza, Great Basin of the Nile* (1866); H. H. Johnston, *The Nile Quest* (1903); D. Middleton, *Baker of the Nile* (1949); J. N. L. Baker, "Sir Richard Burton and the Nile Sources," *English Historical Review*, 59:48–61 (Jan. 1944). (D. Mn.)

END OF VOLUME TWENTY

PRINTED IN THE U. S. A. BY R. R. DONNELLEY & SONS CO.

Encyclopædia Britannica;

OR, A

DICTIONARY

OF

ARTS and SCIENCES,

COMPILED UPON A NEW PLAN.

IN WHICH

The different Sciences and Arts are digested into distinct Treatises or Systems;

AND

The various Technical Terms, &c. are explained as they occur in the order of the Alphabet.

ILLUSTRATED WITH ONE HUNDRED AND SIXTY COPPERPLATES.

By a Society of Gentlemen in Scotland.

IN THREE VOLUMES.

VOL. I.

EDINBURGH:
Printed for A. Bell and C. Macfarquhar;
And sold by Colin Macfarquhar, at his Printing-office, Nicolson-Street.
M.DCC.LXXI.
